The outer envelope of HIV contains *glycoproteins* that are needed for attachment to host cells. Each glycoprotein consists of two subunits, known as *gp41* and *gp120*. The smaller protein (gp41) is embedded in the lipid bilayer of the viral envelope; the larger protein (gp120) is connected firmly to gp41. (The numbers 41 and 120 simply indicate the mass of these glycoproteins in thousands of daltons.)

94.1.1.3 Replication Cycle of HIV

The replication cycle of HIV is depicted in [Figure 93-2](#). The numbers below correspond to the steps in the figure.

- *Step 1*—The cycle begins with attachment of HIV to the host cell. The primary connection takes place between *gp120* on the HIV envelope and a *CD4* protein on the host cell membrane. Other host proteins, known as co-receptors, act in concert with CD4 to tighten the bond with HIV. Two of these co-receptors—known as CCR5 and CXCR4—are of particular importance. A new drug—maraviroc—blocks viral entry by binding CCR5.
- *Step 2*—The lipid bilayer envelope of HIV fuses with the lipid bilayer of the host cell membrane. Fusion is followed by release of HIV RNA into the host cell. In 2003, the first HIV fusion inhibitor became available for general use.

- *Step 3*—HIV RNA is transcribed into single-stranded DNA by HIV *reverse transcriptase*. Eleven of the antiretroviral drugs in current use inhibit this enzyme.
- *Step 4*—Reverse transcriptase converts the single strand of HIV DNA into double-stranded HIV DNA.
- *Step 5*—Double-stranded HIV DNA becomes integrated into the host's DNA, under the direction of a viral enzyme known (aptly) as *integrase*. A new drug—raltegravir—inhibits this enzyme.
- *Step 6*—HIV DNA undergoes transcription into RNA. Some of the resulting RNA becomes the genome for daughter HIV virions (step 6a). The rest of the RNA is messenger RNA that codes for HIV proteins (step 6b).
- *Step 7*—Messenger RNA is translated into HIV glycoproteins (step 7a) and HIV enzymes and structural proteins (step 7b).
- *Step 8*—The components of HIV migrate to the cell surface and assemble into a new virus. Prior to virus assembly, HIV glycoproteins become incorporated into the host cell membrane (step 8a). In steps 8b and 8c, the other components of the virion migrate to the cell surface, where they undergo assembly into the new virus.
- *Step 9*—The newly formed virus buds off from the host cell. As indicated, the outer envelope of the virion is derived from the cell membrane of the host.
- *Step 10*—In this step, which occurs either during or immediately after budding off, HIV undergoes final maturation under the influence of protease, an enzyme that cleaves certain large polyproteins into their smaller, functional forms. If protease fails to cleave these proteins, HIV will remain immature and noninfectious. HIV protease is the target of several important drugs.

94.1.1.4 Replication Rate

HIV replicates rapidly during *all* stages of the infection. During the initial phase of infection, replication is massive. Why? Because (1) the population of CD4 cells is still large, thereby

1088

Figure 93-1 Structure of the human immunodeficiency virus. Note that HIV has two single strands of RNA, and that each strand is associated with a molecule of reverse transcriptase. (gp41 = glycoprotein 41, gp120 = glycoprotein 120.)

providing a large viral breeding ground; and (2) the host has not yet mounted an immune response against HIV, hence replication can proceed unopposed. As a result of massive replication, plasma levels of HIV can exceed 10 million virions/mL. During this stage of high viral load, patients often experience an *acute retroviral syndrome* (see below).

Over the next few months, as the immune system begins to attack HIV, plasma levels of HIV undergo a sharp decline and then level off. A typical steady-state level is between 1000 and 100,000 virions/mL. Please note, however, that steady-state numbers can be deceptive. The plasma half-life of HIV is only 6 hours; that is, every 6 hours, half of the HIV virions in plasma are lost. Accordingly, in order to maintain the steady-state levels typically seen during chronic

HIV infection, the actual rate of *replication* is between 1 and 10 *billion* virions/day. Despite this high rate of ongoing replication, infected individuals typically remain asymptomatic for about 10 years, after which symptoms of advanced HIV disease appear.

94.1.1.5 Mutation and Drug Resistance

HIV mutates rapidly. Why? Because HIV reverse transcriptase is an error-prone enzyme. Hence, whenever it transcribes HIV RNA into single-stranded DNA and then into double-stranded DNA, there is a high probability of introducing base-pair errors. In fact, according to one estimate, up to 10 incorrect bases may be incorporated into HIV DNA during each round of replication. Because of these errors, HIV can rapidly mutate from a drug-sensitive form into a drug-resistant form. The probability of developing resistance in the individual patient is directly related to the total viral load. Hence, the more virions the patient harbors, the greater the likelihood that at least one will become resistant. To minimize the emergence of resistance, patients must be treated with a combination of antiretroviral drugs. This is the same strategy we employ to prevent emergence of resistance when treating tuberculosis (see [Chapter 89](#)).

94.1.2 Transmission of HIV

HIV is transmitted sexually and by other means. The virus is present in all body fluids of infected individuals. Transmission can be via intimate contact with semen, vaginal secretions, and blood. The disease can be transmitted by sexual contact, transfusion, sharing IV needles, and accidental needle sticks. In addition, it can be transmitted to the fetus by an infected mother, usually during the perinatal period. Initially, HIV infection was limited largely to homosexual males, injection drug users, and hemophiliacs. However, the disease can now be found routinely in the population at large. The risk of contracting HIV can be greatly reduced by using condoms and by screening blood supplies for HIV.

94.1.3 Clinical Course of HIV Infection

HIV infection follows a triphasic clinical course. During the initial phase, HIV undergoes massive replication, causing blood levels of HIV to rise very high. As a result, between 50% and 90% of patients experience a flu-like *acute retroviral*

1089

Figure 93-2 Replication cycle of the human immunodeficiency virus. See text for description of events. (CCR5 = CCR5 co-receptor, CD4 = CD4 receptor, CXCR4 = CXCR4 co-receptor, dsDNA = double-stranded DNA, gp120 = glycoprotein 120, mRNA = messenger RNA, ssDNA = single-stranded DNA, ssRNA = single-stranded RNA.)

syndrome. Signs and symptoms include fever, lymphadenopathy, pharyngitis, rash, myalgia, and headache ([Table 93-1](#)). Soon, however, the immune system mounts a counterattack, causing HIV levels to fall. As a result, symptoms of the acute syndrome fade. Very often, the acute retroviral syndrome is perceived as influenza, and hence goes unrecognized for what it really is.

The middle phase of HIV infection is characterized by prolonged *clinical latency*. Blood levels of HIV remain relatively low, and most patients are asymptomatic. However, as noted above, HIV continues to replicate despite apparent dormancy. Because of persistent HIV replication, CD4 T cells undergo progressive decline. The average duration of clinical latency is 10 years.

1090

TABLE 93-1 Acute Retroviral Syndrome: Associated Signs and Symptoms

<ul style="list-style-type: none"> • Fever (96%) • Lymphadenopathy (74%) • Pharyngitis (70%) • Rash and mucocutaneous ulceration (70%) • Erythematous maculopapular rash with lesions on face and trunk and sometimes extremities, including palms and soles <ul style="list-style-type: none"> • Mucocutaneous ulceration involving mouth, esophagus, or genitals • Myalgia or arthralgia (54%) • Diarrhea (32%) • Headache (32%) • Nausea and vomiting (27%) • Hepatosplenomegaly (14%) • Weight loss (13%) • Thrush (12%) • Neurologic symptoms (12%) • Meningoencephalitis or aseptic meningitis <ul style="list-style-type: none"> • Peripheral neuropathy or radiculopathy • Facial palsy • Guillain-Barré neuritis • Brachial neuritis • Cognitive impairment or psychosis

During the late phase of HIV infection, CD4 T cells drop below a critical level (200 cells/mL), rendering the patient highly vulnerable to opportunistic infections and certain neoplasms (eg, Kaposi's sarcoma). The late phase is when AIDS occurs.

Many patients with HIV infection experience neurologic complications. Both the peripheral and central nervous systems may be involved. *Peripheral neuropathies* affect 20% to 40% of patients and may develop at any time over the course of HIV infection. In contrast, *CNS complications* usually occur late in the disease. Symptoms of CNS injury include decreased cognition, reduced concentration, memory loss, mental slowness, and motor complaints (eg, ataxia, tremors). Neuronal injury may be the direct result of HIV infection, or may develop secondary to an opportunistic infection in the CNS.

94.2 CLASSIFICATION OF ANTIRETROVIRAL DRUGS

At this time, we have five types of antiretroviral drugs. Three types—*reverse transcriptase inhibitors*, *integrase inhibitors*, and *protease inhibitors* (PIs)—inhibit enzymes required for HIV replication. The other two types—*fusion inhibitors* and *CCR5 antagonists*—block viral entry into cells. As discussed below, the reverse transcriptase inhibitors are subdivided into two groups: *nucleoside/nucleotide reverse transcriptase inhibitors* (NRTIs), which are structural analogs of nucleosides or nucleotides and (2) *non-nucleoside reverse transcriptase inhibitors* (NNRTIs). Drugs that belong to these groups are listed in [Table 93-2](#). All NRTIs, NNRTIs, PIs, CCR5 antagonists, and integrase inhibitors are administered orally, and one NRTI—zidovudine—may also be given IV. The one fusion inhibitor available—enfuvirtide [Fuzeon]—is administered subQ.

94.3 NUCLEOSIDE/NUCLEOTIDE REVERSE TRANSCRIPTASE INHIBITORS

The nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs) were the first drugs used against HIV infection, and remain mainstays of therapy today. In fact, these drugs constitute the backbone of all treatment regimens. As their name suggests, the NRTIs are chemical relatives of naturally occurring nucleosides or nucleotides, the building blocks of DNA. Antiretroviral effects derive from suppressing synthesis of viral DNA by reverse transcriptase. To be effective, all of the NRTIs must first undergo intracellular conversion to their active (triphosphate) forms. The NRTIs have few drug interactions, and most can be taken without regard to meals. Rarely, these agents cause a potentially fatal syndrome characterized by lactic acidosis and hepatomegaly with steatosis; pregnant women taking two NRTIs may be at increased risk. At this time, eight NRTIs are approved for general use. Major properties are summarized in [Table 93-3](#).

94.3.1 Zidovudine

Zidovudine [Retrovir] was the first NRTI available and will serve as our prototype for the group. The drug is an analog of thymidine, a naturally occurring nucleoside. When employed in combination with other antiretroviral drugs, zidovudine can decrease viral load, increase CD4 T-

cell counts, delay onset of disease symptoms, and reduce symptom severity. The drug's principal dose-limiting toxicities are *severe anemia* and *neutropenia*. Abbreviations for this agent are ZDV (for zidovudine) and AZT (for azidothymidine, its original name).

94.3.1.1 Mechanism of Antiviral Action

Zidovudine inhibits HIV replication by suppressing synthesis of viral DNA. To do this, zidovudine must first undergo intracellular conversion to its active form, zidovudine triphosphate (ZTP). As ZTP, the drug acts as a substrate for reverse transcriptase. However, when ZTP becomes incorporated into the growing DNA strand, it prevents reverse transcriptase from adding more bases; hence, further growth of the strand is blocked. In addition to causing premature strand termination, ZTP competes with natural nucleoside triphosphates for binding to the active site of reverse transcriptase; the result is competitive inhibition of the enzyme.

94.3.1.2 Therapeutic Use

Zidovudine is indicated for HIV infection. This agent penetrates to the CNS better than most other antiretroviral drugs, and hence can be especially valuable for relieving cognitive symptoms. Because monotherapy with any antiretroviral drug can rapidly lead to resistance, zidovudine should always be combined with other antiretroviral agents. The role of zidovudine and other agents in the management of HIV infection is discussed at length later in the chapter.

94.3.1.3 Pharmacokinetics

Zidovudine is readily absorbed following oral administration and distributes to all body tissues, including the CNS. After entering the blood, some of the drug is taken up by cells and converted to ZTP, the active form. The remainder undergoes rapid hepatic conversion to an inactive metabolite. Both zidovudine and its inactive metabolite are eliminated by renal excretion. The *plasma* half-life of the drug is 1.1 hours, and the *intracellular* half-life is 7 hours.

1091

TABLE 93-2 Classification of Antiretroviral Drugs

Generic Name	Trade Name	Chemical Name/Abbreviation
DRUGS THAT INHIBIT HIV ENZYMES		
Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs)		
Single-Drug Products		
Abacavir	Ziagen	ABC
Didanosine	Videx	Dideoxyinosine, ddl
Emtricitabine	Emtriva	FTC
Lamivudine	Epivir	3TC
Stavudine	Zerit	d4T
Tenofovir	Viread	PMPA, TDF
Zalcitabine*	Hivid	Dideoxycytidine, ddC
Zidovudine	Retrovir	Azidothymidine, AZT, ZDV
Fixed-Dose Combinations		
Abacavir/lamivudine	Epzicom	
Abacavir/lamivudine/zidovudine	Trizivir	
Emtricitabine/tenofovir	Truvada	
Zidovudine/lamivudine	Combivir	
Emtricitabine/tenofovir/efavirenz†	Atripla	
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
Delavirdine	Rescriptor	DLV
Efavirenz	Sustiva	EFV
Etravirine	Intelence	ETR
Nevirapine	Viramune	NVP
Protease Inhibitors		
Amprenavir	Agenerase	APV
Atazanavir	Reyataz	ATV
Darunavir	Prezista	DRV
Fosamprenavir	Lexiva	f-APV
Indinavir	Crixivan	IDV, MK-639
Nelfinavir	Viracept	NFV

Ritonavir	Norvir	RTV, ABT-538
Saquinavir	Invirase	SQV
Tipranavir	Aptivus	TPV
Lopinavir/ritonavir	Kaletra	LPV/r
Integrase Inhibitor		
Raltegravir	Isentress	RAL
DRUGS THAT BLOCK HIV ENTRY INTO CELLS		
Fusion Inhibitor		
Enfuvirtide	Fuzeon	T-20
CCR5 Antagonist		
Maraviroc	Selzentry	MAR

* Voluntarily withdrawn in 2006.

† Efavirenz is an NNRTI, not an NRTI.

94.3.1.4 Adverse Effects

94.3.1.4.1 Anemia and Neutropenia from Bone Marrow Suppression.

Severe anemia and neutropenia are the principal toxic effects. Multiple transfusions may be required. The risk of hematologic toxicity is increased by high-dose therapy, advanced HIV infection, deficiencies in vitamin B₁₂ and folic acid, and concurrent use of drugs that are myelosuppressive, nephrotoxic, or directly toxic to circulating blood cells. Anemia and neutropenia generally resolve following zidovudine withdrawal.

Hematologic status (hemoglobin concentration and neutrophil counts) should be determined before treatment and at least every 4 weeks thereafter. Hemoglobin levels may fall significantly within 2 to 4 weeks; neutrophil counts may not fall until after week 6. For patients who develop severe anemia (hemoglobin below 5 gm/dL or down 25% from baseline) or severe neutropenia (neutrophil count below 750 cells/mL or down 50% from baseline), zidovudine should be interrupted until there is evidence of bone marrow recovery. If neutropenia and anemia are less severe, a reduction in dosage may be sufficient. Transfusions may permit some patients to continue drug use.

Granulocyte colony-stimulating factors may be given to reverse zidovudine-induced neutropenia. Also, if erythropoietin levels are not already elevated, *epoetin alfa* (recombinant

erythropoietin) can be given to reduce transfusion requirements in patients with anemia. Granulocyte colony-stimulating factors and epoetin alfa are discussed in [Chapter 55](#).

1092

94.3.1.4.2 Lactic Acidosis with Hepatic Steatosis.

1093

Rarely, zidovudine causes a syndrome of lactic acidosis with severe hepatomegaly (liver enlargement) and hepatic steatosis (fatty degeneration of the liver). Symptoms include nausea, vomiting, abdominal pain, malaise, fatigue, anorexia, and hyperventilation (blowing off carbon dioxide can reduce acidosis). Left untreated, the syndrome can be fatal. Diagnosis is based on lactic acid measurement in *arterial* blood. If clinically significant lactic acidosis is present, zidovudine should be discontinued. Lactic acidosis is caused by toxicity to mitochondria.

Combining NRTIs during pregnancy may increase the risk of lactic acidosis. Several fatalities have occurred in pregnant women who were taking the NRTIs didanosine and stavudine. Because lactic acidosis and hepatic steatosis are potential side effects of *all* NRTIs, it may be prudent to avoid combining any of these drugs during pregnancy.

94.3.1.4.3 Other Adverse Effects.

Gastrointestinal effects (anorexia, nausea, vomiting, diarrhea, abdominal pain, stomach upset) occur on occasion. Possible *CNS reactions* include headache, insomnia, confusion, anxiety, nervousness, and seizures. *Myopathy* (damage to muscle fibers) may also occur.

94.3.1.5 Drug Interactions

Drugs that are myelosuppressive, nephrotoxic, or directly toxic to circulating blood cells can increase the risk of zidovudine-induced hematologic toxicity. Notable among these is *ganciclovir*, an antiviral agent used to treat cytomegalovirus retinitis, a common infection in patients with AIDS. Other drugs of concern include dapsone, pentamidine, pyrimethamine, trimethoprim/sulfamethoxazole, amphotericin B, flucytosine, vincristine, vinblastine, and doxorubicin.

94.3.1.6 Preparations, Dosage, and Administration

94.3.1.6.1 Preparations.

Zidovudine [Retrovir] is available in capsules (100 mg), tablets (300 mg), and a syrup (10 mg/mL) for oral therapy and in solution (10 mg/mL) for IV use. The drug is also available in

combination with lamivudine under the trade name Combivir, and in combination with lamivudine and abacavir under the trade name Trizivir.

94.3.1.6.2 Oral Therapy.

The recommended dosage is 300 mg twice a day or 200 mg 3 times a day. The dosage for treating CNS effects (cognitive slowing, motor slowing, dementia) is 1200 mg/day (ie, twice the normal dosage).

Hematologic monitoring should be done every 2 weeks. If severe anemia or severe neutropenia develops, treatment should be interrupted until there is evidence of bone marrow recovery. If anemia or neutropenia is mild, a reduction in dosage may be sufficient.

94.3.1.6.3 Intravenous Therapy.

Intravenous zidovudine is indicated for adults with AIDS who have a history of cytologically confirmed *Pneumocystis* pneumonia or a CD4 T-cell count below 200 cells/mL. The IV dosage is 1 to 2 mg/kg (infused over 1 hour) every 4 hours around-the-clock. Rapid infusion and bolus injection must be avoided. Intravenous therapy should be stopped as soon as oral therapy is appropriate.

Intravenous solutions are prepared by withdrawing the calculated dose from the stock vial and diluting it to 4 mg/mL (or less) in 5% dextrose for injection. The solution should not be mixed with biologic or colloidal fluids (eg, blood products, protein solutions) and should be administered within 8 hours (if held at room temperature) or within 24 hours (if held under refrigeration).

94.3.2 Other NRTIs

94.3.2.1 Didanosine

94.3.2.1.1 Actions and Uses.

Didanosine [Videx, Videx EC], also known as dideoxyinosine (ddI), is an analog of inosine, a naturally occurring nucleoside. The drug is taken up by host cells, where it undergoes conversion to its active form, dideoxyadenosine triphosphate (ddATP). Like the active form of zidovudine, ddATP suppresses viral replication primarily by causing premature termination of the growing DNA strand. In addition, ddATP competes with natural nucleoside triphosphates for binding to the active center of reverse transcriptase, and thereby

further suppresses DNA synthesis. In clinical trials, didanosine increased CD4 T-cell counts, decreased viremia, and reduced symptoms in patients with AIDS.

Didanosine is approved only for HIV infection. Because monotherapy with any antiretroviral drug can rapidly lead to resistance, the regimen should always include other antiretroviral agents.

94.3.2.1.2 Pharmacokinetics.

Didanosine is administered orally, and bioavailability is low (about 35%). Absorption is greatly reduced by food and gastric acidity. To decrease gastric acidity, and thereby enhance absorption, older formulations of didanosine [Videx] contain buffering agents; newer formulations [Videx EC] are protected by an enteric coating. Didanosine crosses the blood-brain barrier poorly; levels in cerebrospinal fluid are only 20% of those in plasma. Much of the drug (35% to 60%) is excreted unchanged in the urine. The plasma half-life in patients with normal renal function is 1.5 hours, but is 3 times longer in patients with renal failure. The intracellular half-life is more than 20 hours.

94.3.2.1.3 Adverse Effects.

94.3.2.1.3.1 Pancreatitis.

Pancreatitis, which can be fatal, is the major dose-limiting toxicity. The incidence is 3% to 17%. Patients should be monitored for indications of developing pancreatitis (increased serum amylase in association with increased serum triglycerides; decreased serum calcium; and nausea, vomiting, or abdominal pain). If evolving pancreatitis is diagnosed, didanosine should be withdrawn. The risk of pancreatitis is increased by a history of pancreatitis or alcoholism and by use of IV pentamidine. Caution should be exercised in such patients.

94.3.2.1.3.2 Lactic Acidosis with Hepatic Steatosis.

Like all other NRTIs, didanosine can cause lactic acidosis with hepatic steatosis. Fatalities have occurred in several pregnant women taking didanosine plus stavudine. Accordingly, the manufacturer warns against combining these drugs during pregnancy, unless resistance to all other antiretrovirals leaves no option. Because lactic acidosis and hepatic steatosis are potential side effects of *all* NRTIs, it may be prudent to avoid combining didanosine with any of these drugs during pregnancy.

94.3.2.1.3.3 Other Adverse Effects.

Additional adverse effects include diarrhea (28%), peripheral neuropathy (20%), chills or fever (12%), and rash or pruritus (9%). In contrast to zidovudine, didanosine causes minimal bone marrow suppression.

94.3.2.1.4 Drug Interactions.

For treatment of HIV infection, didanosine can be used in various regimens (see [Table 93-8 on p. 1114](#)). Buffered didanosine formulations can interfere with the absorption of drugs that require gastric acidity, including delavirdine and indinavir. Ribavirin can increase levels of didanosine, and may thereby pose a risk of toxicity. Accordingly, the combination should be used with caution.

94.3.2.1.5 Preparations, Dosage, and Administration.

Didanosine is available in three formulations: buffered chewable tablets [Videx], enteric-coated capsules [Videx EC], and a buffered powder for oral solution [Videx].

94.3.2.1.5.1 All Formulations.

Because absorption is greatly reduced by food, didanosine should be administered on an empty stomach, either 30 minutes before meals or 2 hours after. Because didanosine is eliminated by the kidneys, dosage must be reduced in patients with renal impairment.

94.3.2.1.5.2 Buffered Chewable Tablets.

Didanosine tablets [Videx] are available in five strengths: 25, 50, 100, 150, and 200 mg. Instruct patients to either (1) chew the tablets thoroughly, or (2) manually crush them or disperse them in at least 1 ounce of water. Dosage is based on body weight. For adults over 60 kg, the dosage is 400 mg once daily or 200 mg twice daily. For adults under 60 kg, the dosage is 250 mg once daily or 125 mg twice daily. To ensure adequate buffering of gastric acid, patients must take two tablets (of appropriate size) for each dose.

94.3.2.1.5.3 Enteric-Coated Capsules.

Didanosine enteric-coated capsules [Videx EC] are available in four strengths: 125, 200, 250, and 400 mg. Dosage is 400 mg once daily (for patients over 60 kg) and 250 mg once

daily (for patients under 60 kg). In contrast to the buffered tablets, which must be crushed or chewed, the enteric-coated capsules must be swallowed intact.

94.3.2.1.5.4 Buffered Powder for Oral Solution.

Didanosine powder for oral solution is available in single-dose packets (100, 167, and 250 mg) and in bottles (2 and 4 gm) for pediatric use. Instruct patients using the single-dose packets to (1) pour the contents of one packet into 4 ounces of water (not fruit juice or any other acid-containing beverage); (2) stir the mixture until the drug dissolves (about 2 to 3 minutes); and (3) drink the solution immediately. Dosage is 250 mg twice daily (for patients over 60 kg) or 167 mg twice daily (for patients under 60 kg).

94.3.2.2 Stavudine

94.3.2.2.1 Actions and Uses.

Stavudine [Zerit, Zerit XR], also known as didehydrodeoxythymidine (d4T), is an analog of thymidine, a naturally occurring nucleoside. Following uptake by cells, stavudine is converted to its active form, stavudine triphosphate. The active drug then suppresses HIV replication by (1) causing premature termination of the growing DNA strand and (2) competing with natural nucleoside triphosphates for binding to reverse transcriptase.

1093

Adapted from *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, prepared by the Panel on Clinical Practices for Treatment of HIV Infection convened by the DHHS, October 6, 2005.

* Lactic acidosis with hepatic steatosis is a rare but potentially fatal toxicity associated with *all* NRTIs.

† EC = enteric coated.

‡ XR = extended release.

Stavudine is an effective drug for HIV infection. Like all other drugs used against HIV, stavudine should be combined with other antiretroviral agents to decrease the risk of resistance.

94.3.2.2.2

Pharmacokinetics.

Stavudine is administered orally, and bioavailability is high (86%). Food has little or no effect on absorption. Penetration to the CNS is good. Elimination is by a combination of hepatic metabolism and renal excretion. The plasma half-life is 1 hour, and the intracellular half-life is 7.5 hours.

94.3.2.2.3 Adverse Effects.

94.3.2.2.3.1 Peripheral Neuropathy.

Like didanosine, stavudine can cause peripheral neuropathy. In clinical trials, neuropathy developed in 15% to 21% of patients. Patients should be informed about early symptoms of neuropathy (numbness, tingling, or pain in hands and feet) and instructed to report them immediately. Neuropathy may resolve if the drug is withdrawn. If symptoms resolve completely, resumption of treatment may be considered, but the dosage should be reduced.

94.3.2.2.3.2 Pancreatitis.

Stavudine can cause pancreatitis. Although the incidence is low (1%), pancreatitis can be fatal. Patients should be monitored for indications of pancreatitis, and, if evolving pancreatitis is diagnosed, stavudine should be withdrawn.

94.3.2.2.3.3 Lactic Acidosis with Hepatic Steatosis.

Like all other NRTIs, stavudine can cause lactic acidosis and hepatic steatosis. In fact, the incidence with stavudine may be higher than with all other NRTIs. As noted, fatal lactic acidosis has developed in several pregnant women taking stavudine plus didanosine. Accordingly, the manufacturer warns against combining these drugs during pregnancy, unless resistance to all other antiretrovirals leaves no option. Because lactic acidosis is a potential side effect of *all* NRTIs, it may be prudent to avoid combining stavudine with any NRTI during pregnancy.

94.3.2.2.3.4 Neuromuscular Weakness.

Rarely, stavudine causes ascending demyelinating polyneuropathy, resulting in neuromuscular weakness. Symptoms begin months after initiation of treatment, but then progress rapidly, producing dramatic motor weakness within days to weeks. Some patients may require mechanical ventilation owing to respiratory paralysis. Patients who experience symptoms should discontinue all antiretroviral drugs. Recovery takes several months, and may never be complete.

94.3.2.2.4 Drug Interactions.

Like stavudine, *didanosine* can cause peripheral neuropathy. Accordingly, the combination should be used with caution.

94.3.2.2.5 Preparations, Dosage, and Administration.

Stavudine is available in standard capsules (15, 20, 30, and 40 mg) sold as Zerit, extended-release capsules (37.5, 50, 75, and 100 mg) sold as Zerit XR, and a powder (1 mg/mL) for making an oral solution. Dosage for the standard capsules and oral solution is 40 mg twice a day (for patients over 60 kg) or 30 mg twice a day (for patients under 60 kg). Dosage for the extended-release capsules is 100 mg once a day (for patients over 60 kg) or 75 mg once a day (for patients under 60 kg). Stavudine may be administered with or without food.

1094

94.3.2.3 Lamivudine

1095

94.3.2.3.1 Actions and Uses.

Lamivudine [Epivir], also known as dideoxy3'-thiacytidine (3TC), is an analog of cytidine, a naturally occurring nucleoside. Following uptake by cells, the drug is converted to its active form, lamivudine triphosphate, which then suppresses HIV replication by (1) causing premature termination of the growing DNA strand and (2) competing with natural nucleoside triphosphates for binding to reverse transcriptase.

Lamivudine is approved for HIV infection and also for hepatitis B. (The formulation used for hepatitis is marketed as Epivir HBV [see [Chapter 92](#)]). Like all other drugs used against HIV, lamivudine should be combined with at least one other antiretroviral agent, so as to decrease the risk of resistance.

94.3.2.3.2 Pharmacokinetics.

Lamivudine is administered orally, and bioavailability is high (86%). Food slows the rate of absorption but does not decrease the extent. The drug is eliminated intact in the urine. The plasma half-life is 5 to 7 hours, and the intracellular half-life is 18 to 22 hours.

94.3.2.3.3 Adverse Effects.

Of all the NRTIs, lamivudine is the best tolerated. Side effects are minimal. Some patients experience insomnia and headache, but these effects usually fade in a few weeks.

Like all other NRTIs, lamivudine poses a small risk of potentially fatal lactic acidosis. Combining NRTIs may increase the risk of lactic acidosis in pregnant women, and hence should be avoided when feasible.

94.3.2.3.4 Preparations, Dosage, and Administration.

For treatment of HIV, lamivudine [Epivir] is available in tablets (150 and 300 mg) and an oral solution (10 mg/mL). The drug is also available in combination with zidovudine under the trade name Combivir, and in combination with abacavir and zidovudine under the trade name Trizivir. The dosage for adults is 300 mg/day, administered as 150 mg twice daily or 300 mg once daily. The dosage for children ages 3 months to 16 years is 4 mg/kg twice daily (up to a maximum of 150 mg twice daily). In patients with renal impairment, dosage should be reduced. Lamivudine may be administered with or without food.

94.3.2.4 Abacavir

94.3.2.4.1 Actions and Use.

Abacavir [Ziagen], also known as ABC, is an analog of guanine, a naturally occurring pyrimidine. The drug is taken up by host cells, where it undergoes conversion to its active form, carbovir triphosphate, an analog of deoxyguanosine triphosphate. Carbovir triphosphate suppresses viral replication by causing premature termination of the growing DNA strand and by competing with natural nucleoside triphosphates for binding to the active center of reverse transcriptase.

Abacavir is approved only for HIV infection. Because monotherapy with any antiretroviral drug can rapidly lead to resistance, abacavir should always be combined with other antiretroviral agents.

94.3.2.4.2 Pharmacokinetics.

Abacavir is administered orally, and bioavailability is high (83%). Absorption is not affected by food. Penetration to cerebrospinal fluid is good. The drug is converted to inactive metabolites by *alcohol dehydrogenase*. Metabolites are excreted in the urine. The plasma half-life is 1.5 hours, and the intracellular half-life is 12 to 26 hours.

1095

1096

94.3.2.4.3 Adverse Effects.

94.3.2.4.3.1 Hypersensitivity Reactions.

Hypersensitivity reactions occur in 5% to 8% of patients. These reactions, which usually develop during the first 6 weeks of treatment, can be severe and even fatal. Symptoms include fever, rash (typically maculopapular or urticarial), myalgia, arthralgia, and GI

disturbances (nausea, vomiting, diarrhea, abdominal pain). A severe reaction can result in liver failure, renal failure, anaphylaxis, and death. If a hypersensitivity reaction occurs, abacavir should be withdrawn and never used again.

Abacavir hypersensitivity reactions can manifest initially as *respiratory symptoms* (eg, pharyngitis, dyspnea, cough). Because abacavir hypersensitivity can rapidly prove fatal, early recognition is critical. Accordingly, if respiratory symptoms develop, abacavir hypersensitivity should be suspected, even though alternative diagnoses (eg, pneumonia, bronchitis, pharyngitis, flu-like illness) are possible. If a clear differentiation between acute respiratory illness and abacavir hypersensitivity cannot be made, abacavir should be withdrawn and never used again.

A specific genetic variation, known as HLA-B*5701, is strongly associated with abacavir hypersensitivity. Therefore, all candidates for abacavir should be screened for this variation. Patients who test positive for HLA-B*5701 should not receive the drug, and abacavir hypersensitivity should be noted on their allergy list. Those who test negative are less likely to experience hypersensitivity, but should be counseled about the symptoms of the reaction nonetheless.

94.3.2.4.3.2

Other Adverse Effects.

Abacavir can cause nausea (13%), nausea with vomiting (9%), diarrhea (7%), and headache (10%). Like all other NRTIs, abacavir poses a small risk of potentially fatal lactic acidosis with hepatic steatosis. Combining NRTIs may increase the risk of lactic acidosis in pregnant women, and hence should be avoided when feasible. Abacavir has been associated with an increased risk of myocardial infarction, and should be considered carefully in patients with underlying coronary heart disease or other cardiovascular risk factors.

94.3.2.4.4

Drug Interactions.

Alcohol can compete with abacavir for metabolism by alcohol dehydrogenase, and can thereby increase abacavir levels substantially (about 40%). The clinical significance of this interaction is unclear. Nonetheless, it would seem prudent to minimize alcohol consumption.

Significant interactions with drugs other than alcohol have not been reported.

94.3.2.4.5 Preparations, Dosage, and Administration.

94.3.2.4.5.1 Preparations.

Abacavir [Ziagen] is available in 300-mg tablets and a 20-mg/mL oral solution. In addition, abacavir is available in combination with lamivudine under the name Epzicom, and in combination with zidovudine and lamivudine under the name Trizivir.

94.3.2.4.5.2 Dosage and Administration.

Abacavir may be taken without regard to meals. The adult dosage is 300 mg twice daily or 600 mg once daily. The pediatric dosage is 8 mg/kg twice daily, but should not exceed 300 mg twice daily.

94.3.2.5 Tenofovir Disoproxil Fumarate

94.3.2.5.1 Mechanism of Action.

Tenofovir disoproxil fumarate (tenofovir DF) [Viread] is a *nucleotide* reverse transcriptase inhibitor—not a *nucleoside* reverse transcriptase inhibitor. The drug is discussed in this section because nucleotides and nucleosides are very similar (a nucleotide is simply a nucleoside with a phosphate group added) and hence have similar effects on reverse transcriptase. Once inside cells, tenofovir DF undergoes conversion to tenofovir, and then to tenofovir diphosphate, its active form. Like the NRTIs, tenofovir diphosphate inhibits viral DNA synthesis in two ways: (1) it competes with the natural substrate (in this case, deoxyadenosine triphosphate) for binding to reverse transcriptase, and (2) after being incorporated into the growing DNA chain, it causes premature chain termination. Toxicity results in part from inhibiting mitochondrial DNA polymerase.

94.3.2.5.2 Therapeutic Use.

Tenofovir is indicated only for treatment of HIV infection. To delay emergence of resistance, the regimen should always include other antiretroviral drugs.

94.3.2.5.3 Pharmacokinetics.

Tenofovir is administered orally, and bioavailability is low (25% in the absence of food and 39% in the presence of food). Blood levels peak about 1 hour after administration. Binding to plasma proteins is low. Tenofovir is eliminated primarily by the kidneys; both glomerular

filtration and active tubular secretion are involved. Because elimination is renal, tenofovir can accumulate to dangerous levels if kidney function is impaired. Tenofovir has a prolonged half-life—17 hours in plasma and more than 60 hours within cells—and hence can be administered just once a day.

94.3.2.5.4 Adverse Effects.

Tenofovir is generally well tolerated. The most common reactions are mild to moderate GI effects: nausea (11%), diarrhea (9%), vomiting (5%), and flatulence (4%). Asthenia (8%) and headache (6%) may also occur.

Like other NRTIs, tenofovir poses a small risk of potentially fatal *lactic acidosis with hepatic steatosis*. Combining NRTIs may increase risk in pregnant women, and hence should be avoided when feasible.

94.3.2.5.5 Drug Interactions.

Tenofovir has little or no effect on the metabolism of other drugs. However, combining tenofovir with another drug that undergoes active tubular secretion could lead to the accumulation of tenofovir, the other drug, or both. Through a mechanism that has not been determined, tenofovir can raise plasma levels of didanosine. Accordingly, patients using the combination should be monitored for long-term didanosine toxicity.

94.3.2.5.6 Preparations, Dosage, and Administration.

94.3.2.5.6.1 Preparations.

Tenofovir, by itself, is available in 300-mg tablets under the name Viread. The drug is also available in combination with emtricitabine under the name Truvada.

94.3.2.5.6.2 Dosage and Administration.

The recommended dosage is 300 mg once a day, taken without regard to meals. If the patient is also taking didanosine, tenofovir should be administered 2 hours before didanosine or 1 hour after. Patients with significant renal impairment (creatinine clearance below 60 mL/min) should not use the drug.

94.3.2.6 Emtricitabine

94.3.2.6.1 Actions and Uses.

Emtricitabine [Emtriva] is a fluorinated derivative of lamivudine. Like lamivudine, emtricitabine is active against HIV and hepatitis B virus (HBV). Following uptake by cells, emtricitabine is converted to emtricitabine triphosphate, its active form, which inhibits viral DNA synthesis by (1) competing with natural substrates for binding to reverse transcriptase and (2) promoting premature termination of the growing DNA strand. Emtricitabine is a weak inhibitor of mammalian DNA polymerases, both nuclear and mitochondrial. The drug has a long intracellular half-life, and hence dosing can be done just once a day.

94.3.2.6.2 Pharmacokinetics.

Emtricitabine undergoes rapid and nearly complete absorption, both in the presence and absence of food. Plasma levels peak 1 to 2 hours after dosing. Protein binding in blood is minimal, as is hepatic metabolism. Most of each dose is eliminated unchanged in the urine. The plasma half-life is 10 hours, and the intracellular half-life is 39 hours—longer than that of most other NRTIs.

94.3.2.6.3 Adverse Effects.

Emtricitabine is generally well tolerated. The most common adverse effects are headache, diarrhea, nausea, and rash. An unusual side effect—hyperpigmentation of the palms and soles—develops in some patients. Like other nucleoside analogs, emtricitabine may pose a risk of lactic acidosis and severe hepatomegaly with steatosis, usually in women. If either complication arises, emtricitabine should be withdrawn. Because emtricitabine can suppress HBV, patients co-infected with HBV may experience an exacerbation of hepatitis when emtricitabine is discontinued.

94.3.2.6.4 Drug Interactions.

Emtricitabine does not affect cytochrome P450 drug-metabolizing enzymes, and hence is unlikely to interact with other drugs. No significant interactions were noted in patients taking emtricitabine with indinavir, stavudine, famciclovir, or tenofovir.

94.3.2.6.5 Preparations, Dosage, and Administration.

94.3.2.6.5.1 Preparations.

Emtricitabine [Emtriva] is supplied in 200-mg capsules and an oral solution (10 mg/mL). The drug is also available combined with tenofovir under the name Truvada.

94.3.2.6.5.2 Dosage and Administration.

The dosage for patients 18 years and older is 200 mg once a day, taken with or without food. Because emtricitabine is eliminated primarily by the kidneys, the dosing interval should be increased in patients with renal impairment, as indicated by reduced creatinine clearance (CrCl). Specific adjustments are as follows:

- CrCl 50 mL/min or higher—no adjustment needed
- CrCl 30 to 49 mL/min—200 mg every 48 hours
- CrCl 15 to 29 mL/min—200 mg every 72 hours
- CrCl below 15 mL/min—200 mg every 96 hours

94.3.2.7 Zalcitabine

Zalcitabine [Hivid], also known as dideoxycytidine (ddC), is an analog of cytidine, a naturally occurring nucleoside. Zalcitabine is a prodrug that undergoes conversion to its active form (ddC triphosphate) within host cells. The active form inhibits viral DNA synthesis by (1) causing premature termination of the growing DNA strand and (2) competing with natural nucleoside triphosphates for binding to reverse transcriptase. Owing to a high incidence of peripheral neuropathy and the availability of safer drugs, use of zalcitabine declined sharply, leading the manufacturer to withdraw the drug in 2006. For more information on zalcitabine, refer to the sixth edition of this book.

1096

94.3.2.8 Combination Products

1097

94.3.2.8.1 Abacavir/Zidovudine/Lamivudine.

Abacavir, lamivudine, and zidovudine are available in a single tablet under the trade name *Trizivir*. The amount of each drug in the combination is the same as in their individual formulations: abacavir, 300 mg; lamivudine, 150 mg; and zidovudine, 300 mg. Dosing is

done twice a day—the same schedule employed when the drugs are taken separately. The only benefit of the combination is that patients can now take just one pill twice a day, instead of three twice a day. Dosing may be done with or without food. Because dosage of each component cannot be adjusted separately, the product should not be used by patients with renal or hepatic impairment.

Adverse effects are like those seen with each component taken separately. Abacavir can cause potentially fatal *hypersensitivity reactions*. Early manifestations include fever, rash, fatigue, GI symptoms, and respiratory symptoms. If these develop, treatment should be interrupted while an evaluation is conducted. If hypersensitivity cannot be ruled out, the drug should be discontinued permanently. Zidovudine can cause *anemia* and *neutropenia*. Hematologic status should be closely monitored. All nucleosides can cause *lactic acidosis* and *severe hepatomegaly with steatosis*.

94.3.2.8.2 Abacavir/Lamivudine.

Abacavir (600 mg) and lamivudine (300 mg) are available in a single tablet, sold as *Epzicom*, for treating HIV infection in adults. The dosage is 1 tablet once a day. Adverse effects are similar to those seen with each drug taken separately—although the incidence of severe hypersensitivity reactions (from abacavir) may be higher than usual, owing to dosing once daily rather than twice daily. Both components pose a small risk of fatal lactic acidosis and severe hepatomegaly with steatosis. The product is contraindicated for patients with hepatic impairment or renal insufficiency (CrCl below 50 mL/min).

94.3.2.8.3 Emtricitabine/Tenofovir.

Emtricitabine (200 mg) and tenofovir (300 mg) are available in a single tablet, sold as *Truvada*, for treating HIV infection in adults. Adverse effects are similar to those of each drug taken alone. Lactic acidosis and hepatomegaly are the greatest concerns. The dosage for Truvada is 1 tablet once a day, taken with or without food. For patients with renal impairment, dosage must be adjusted as follows: CrCl 30 to 49 mL/min, 1 tablet every 48 hours; CrCl below 30 mL/min (including patients on dialysis), don't use this product.

94.3.2.8.4 Lamivudine/Zidovudine.

Lamivudine (150 mg) and zidovudine (300 mg) are available in a single tablet under the name *Combivir*. The dosage for adults and for children at least 12 years old is 1 tablet twice a day, taken without regard to meals. Because the dosage of each component cannot be adjusted separately, the product should not be used by patients with renal or hepatic

impairment. Principal adverse effects are anemia and neutropenia (caused by zidovudine) and lactic acidosis with hepatic steatosis (caused by both drugs).

94.3.2.8.5 Emtricitabine/Tenofovir/Efavirenz.

This fixed-dose combination, sold as *Atripla*, is the first product to contain drugs from two different antiretroviral classes: emtricitabine (200 mg) and tenofovir (300 mg) are NRTIs, whereas efavirenz (600 mg) is an NNRTI. The combination is a recommended first-line regimen for treatment-naïve patients. Dosing is done just once a day, making Atripla the first *one-pill once-a-day* HIV treatment.

94.4 NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS

The non-nucleoside reverse transcriptase inhibitors (NNRTIs) differ from the NRTIs in structure and mechanism of action. As their name suggests, the NNRTIs are not structurally related to naturally occurring nucleosides. Also, in contrast to the NRTIs, which inhibit synthesis of HIV DNA primarily by causing premature termination of the growing DNA strand, the NNRTIs bind to the active center of reverse transcriptase, and thereby cause direct inhibition. Furthermore, whereas NRTIs must undergo intracellular conversion to their active forms, the NNRTIs are active as administered. At this time, four NNRTIs are available: efavirenz [Sustiva], nevirapine [Viramune], delavirdine [Rescriptor], and etravirine [Intelence]. The principal adverse effect of these drugs is rash, which can be severe. Pharmacologic properties of the NNRTIs are summarized in [Table 93-4](#).

94.4.1 Efavirenz

Efavirenz [Sustiva] is the only NNRTI deemed a preferred agent for treating HIV. The drug is effective and, because of its long half-life, can be administered once a day. Its principal drawbacks are teratogenicity and transient adverse CNS effects.

94.4.1.1 Mechanism of Action.

Efavirenz binds directly to HIV reverse transcriptase and thereby disrupts the active center of the enzyme. As a result, enzyme activity is suppressed. Efavirenz only inhibits reverse transcriptase of HIV-1; it does not inhibit reverse transcriptase of HIV-2. In addition, efavirenz does not inhibit human DNA polymerases, and hence is harmless to us.

94.4.1.2 Therapeutic Use.

Efavirenz is the only NNRTI recommended as first-line therapy for HIV infection. In clinical trials, the combination of efavirenz plus two NRTIs (zidovudine and lamivudine) was at least

as effective as indinavir (a protease inhibitor) combined with the same two NRTIs. Furthermore, the efavirenz-based regimen was better tolerated.

94.4.1.3 Pharmacokinetics.

Efavirenz is administered orally and should be taken on an empty stomach. Administration with a high-fat meal can increase plasma levels by 39% (using efavirenz capsules) and by 50% (using efavirenz tablets). Plasma levels peak 3 to 5 hours after dosing. In the blood, efavirenz is highly (over 99%) protein bound. The drug crosses the blood-brain barrier and can reduce HIV levels in the CNS. Efavirenz undergoes metabolism by P450, followed by excretion in the urine and feces. The drug has a long serum half-life (40 to 55 hours), and hence can be taken just once a day.

94.4.1.4 Adverse Effects.

CNS symptoms occur in over 50% of patients. The most common are dizziness, insomnia, impaired consciousness, drowsiness, vivid dreams, and nightmares. Delusions, hallucinations, and severe acute depression may also occur, primarily in patients with a history of mental illness or drug abuse. Patients who experience these severe reactions should discontinue the drug. CNS symptoms are prominent at the onset of treatment, but generally resolve within 2 to 4 weeks, despite continuous drug use.

Rash occurs often. In clinical trials, rash developed in 27% of adults and 40% of children. The median time to rash onset was 11 days, and the median duration was 14 days. Rash can range in severity from mild (erythema, pruritus) to moderate (diffuse maculopapular rash, dry desquamation) to severe (vesiculation, moist desquamation, ulceration). Very rarely, patients develop Stevens-Johnson syndrome, which can be fatal. If severe rash occurs, efavirenz should be withdrawn. Rash may respond to antihistamines and topical glucocorticoids.

Efavirenz is *teratogenic*. In monkeys, doses equivalent to those used in humans produced a high incidence of fetal malformation. Women using the drug must avoid getting pregnant. A barrier method of birth control (eg, condom) should be used in conjunction with a hormonal method (eg, oral contraceptive). Pregnancy must be ruled out before efavirenz is used.

Like other NNRTIs, efavirenz may pose a risk of *liver damage*. Liver enzymes should be monitored, especially in patients with hepatitis B or C.

94.4.1.5 Drug Interactions.

Efavirenz can compete with other drugs for metabolism by P450, thereby causing them to accumulate, possibly to dangerous levels. To avoid harm, efavirenz should not be combined with cisapride, alprazolam, midazolam, triazolam, dihydroergotamine, or ergotamine—or with astemizole or terfenadine, which are no longer available in the United States.

Efavirenz *induces P450*, and can thereby accelerate its own metabolism and the metabolism of many other drugs. Increased metabolism of two protease inhibitors—saquinavir and indinavir—is of particular concern. If efavirenz is combined with indinavir, the dosage of indinavir should be increased. Combined use with saquinavir, a drug with low bioavailability, should be avoided.

1097

1099

TABLE 93-4 Properties of Non-nucleoside Reverse Transcriptase Inhibitors

	Efavirenz (EFV)	Nevirapine (NVP)	Delavirdine (DLV)	Etravirine (ETR)
Trade Name	Sustiva	Viramune	Rescriptor	Intelence
Formulations	Capsules: 50, 100, 200 mg Tablets: 600 mg	Tablets: 200 mg PO suspension: 10 mg/mL	Tablets: 100, 200 mg	Tablets: 100 mg
Impact of Food	Take on an empty stomach. High-fat meals increase plasma levels by 39% with capsules and by 79% with tablets.	Take without regard to meals	Take without regard to meals	Take following a meal
Dosage	600 mg on an empty stomach or at bedtime	200 mg once a day for 14 days, then 200 mg twice a day	400 mg 3 times/day (mix four 100-mg tablets in 3 or more ounces of water to produce a slurry)	200 mg (two 100-mg tablets) twice a day
Bioavailability	Data not available	Over 90%	85%	Data not available
Serum Half-life	40–55 hr	25–30 hr	5.8 hr	20–60 hr
Elimination	Metabolized by P450, followed by excretion in the urine (14–34%) and feces (16–61%)	Metabolized by P450, followed by excretion in urine (80%) and feces (10%)	Metabolized by P450, followed by excretion in urine (51%) and feces (44%)	Metabolized by CYP3A4, CYP2C9, and CYP2C19, followed by excretion in urine (1.2%) and feces (93.7%)
Adverse Events	<ul style="list-style-type: none"> • Rash[*] • Increased transaminase levels • CNS symptoms[†] • Teratogenic in monkeys 	<ul style="list-style-type: none"> • Rash[*] • Increased transaminase levels • Hepatitis 	<ul style="list-style-type: none"> • Rash[*] • Increased transaminase levels • Headache 	<ul style="list-style-type: none"> • Rash[*] • Increased transaminase levels • Diarrhea • Nausea • Increased amylase • Elevated creatinine

<p>Drug Interactions</p>	<ul style="list-style-type: none"> • Efavirenz can compete with other drugs for metabolism by P450, thereby causing them to accumulate to toxic levels. Accordingly, efavirenz should not be combined with astemizole,[‡] terfenadine,[‡] cisapride, midazolam, alprazolam, triazolam, or ergot alkaloids. • Efavirenz induces P450, and can thereby decrease levels of saquinavir and indinavir. Don't combine with saquinavir. Increase indinavir dosage. • Combining efavirenz with ritonavir increases levels of both drugs; toxicity can result. • St. John's wort induces P450 and can thereby reduce levels of efavirenz. Don't combine efavirenz with this agent. <ul style="list-style-type: none"> • <i>Induces</i> P450 and may thereby <i>decrease</i> levels of other drugs; effects on protease inhibitors, oral contraceptives, and methadone are of particular concern. • Rifampin and St. John's wort induce P450, and may thereby decrease levels of nevirapine. Don't use nevirapine with these agents. <ul style="list-style-type: none"> • <i>Inhibits</i> P450 and may thereby <i>increase</i> levels of other drugs. • Because of P450 inhibition, the following drugs are <i>contraindicated</i>: astemizole,[‡] terfenadine,[‡] alprazolam, midazolam, triazolam, simvastatin, lovastatin, and cisapride. • Because of P450 inhibition, the following drugs should be used with <i>caution</i>: indinavir, saquinavir, clarithromycin, dapsone, ergot alkaloids, dihydropyridine calcium channel blockers, quinidine, warfarin, and sildenafil [Viagra]. • Antacids, histamine₂-receptor blockers (eg, cimetidine), proton pump inhibitors (eg, omeprazole), and buffered formulations of didanosine can decrease absorption of delavirdine. • Rifampin, rifabutin, and St. John's wort induce <ul style="list-style-type: none"> • The following drugs can decrease etravirine levels: anticonvulsants, darunavir/ritonavir, ritonavir, saquinavir/ritonavir, tipranavir/ritonavir, St. John's wort, and systemic dexamethasone. • The following drugs can increase etravirine levels: intraconazole, ketoconazole, fluconazole, posaconazole, and diazepam.
---------------------------------	--

P450 and can thereby reduce levels of delavirdine substantially. Don't use delavirdine with these agents.

* Rarely, rash evolves into Stevens-Johnson syndrome, which can be fatal.

† CNS symptoms, including dizziness, somnolence, insomnia, abnormal dreams, abnormal thinking, confusion, impaired concentration, amnesia, agitation, depersonalization, hallucinations, and euphoria, occur in about 50% of patients.

‡ No longer available in the United States.

Combining efavirenz with ritonavir (a protease inhibitor that inhibits P450) can increase levels of both drugs. Toxicity may result.

St. John's wort—an herbal supplement taken for depression—may reduce levels of efavirenz and other NNRTIs. The principal mechanism is accelerated metabolism secondary to induction of P450 (see [Chapter 107](#)).

94.4.1.6 Preparations, Dosage, and Administration.

Efavirenz [Sustiva] is available in 600-mg tablets and in capsules (50, 100, and 200 mg). The adult dosage is 600 mg once daily, taken on an empty stomach. To reduce the impact of CNS effects, dosing should be done at bedtime for the first few weeks.

94.4.2 Other NNRTIs

94.4.2.1 Nevirapine

94.4.2.1.1 Mechanism of Action.

Like other NNRTIs, nevirapine [Viramune] binds directly to HIV reverse transcriptase, causing noncompetitive inhibition of the enzyme. Nevirapine is selective for HIV-1. It does not affect HIV-2, and does not inhibit human DNA polymerase.

94.4.2.1.2 Pharmacokinetics.

Nevirapine is well absorbed (over 90%) following oral administration, both in the presence and absence of food. The drug is very lipid soluble, and hence can cross both the placenta and blood-brain barrier, and can enter breast milk with ease. Concentrations achieved in

cerebrospinal fluid are about 45% of those in plasma. Elimination results from hepatic metabolism followed by excretion in the urine (80%) and feces.

94.4.2.1.3 Therapeutic Use and Resistance.

Nevirapine is approved only for treating infection with HIV-1; the drug is not active against HIV-2. Resistance to nevirapine develops rapidly if the drug is used alone. Accordingly, nevirapine should always be combined with other antiretroviral drugs.

94.4.2.1.4 Adverse Effects.

The most common adverse effect is *rash*, which usually occurs early in therapy and can be severe or even life threatening. For most patients, the rash is benign and, if needed, can be managed with an antihistamine or topical glucocorticoid. However, if the patient experiences severe rash or rash associated with fever, blistering, oral lesions, conjunctivitis, muscle pain, or joint pain, nevirapine should be withdrawn. Why? Because these symptoms may indicate development of *erythema multiforme* or *Stevens-Johnson syndrome*. Rash can be minimized by using a low dosage initially and then increasing the dosage if rash does not occur.

Nevirapine can cause severe *hepatotoxicity*, including fulminant and cholestatic hepatitis, hepatic necrosis, and hepatic failure. Fatalities have occurred. The risk is highest during the first 12 weeks of treatment, and is increased by a history of chronic hepatitis B or hepatitis C. Liver function tests should be done at baseline, prior to dosage escalation, 2 weeks after dosage escalation, and whenever patients have symptoms (fatigue, malaise, anorexia, nausea) suggesting an early stage of liver damage. If hepatotoxicity is diagnosed, nevirapine should be withdrawn as soon as possible.

94.4.2.1.5 Drug Interactions.

Nevirapine induces the activity of hepatic cytochrome P450 drug-metabolizing enzymes, and can thereby increase the metabolism of other drugs, causing their levels to decline. The ability to decrease levels of *protease inhibitors*, *oral contraceptives*, and *methadone* is of particular concern.

Like nevirapine, *rifampin* can induce P450, and can thereby significantly reduce nevirapine levels. Accordingly, the combination is not recommended.

St. John's wort induces P450, and can thereby reduce levels of nevirapine. The combination should be avoided.

94.4.2.1.6 Preparations, Dosage, and Administration.

Nevirapine [Viramune] is available in 200-mg tablets and a 10-mg/mL oral suspension.

Dosages are as follows:

- *Adults*—Start with 200 mg once a day for 14 days and then, if no rash develops, use 200 mg twice a day thereafter.
- *Children 8 years and older*—Start with 4 mg/kg once a day for 14 days and then, if no rash develops, use 4 mg/kg twice a day thereafter.
- *Children 2 months to 8 years*—Start with 4 mg/kg once a day for 14 days and then, if no rash develops, use 7 mg/kg (but not more than 400 mg total) twice a day thereafter.

94.4.2.2 Delavirdine

94.4.2.2.1 Actions, Resistance, and Use.

Delavirdine [Rescriptor] is similar to efavirenz in actions and uses. Like efavirenz, delavirdine is a non-nucleoside that acts directly to inhibit reverse transcriptase, thereby suppressing HIV replication. Because resistant forms of HIV rapidly emerge when delavirdine is used alone, the drug should always be combined with other antiretroviral agents. Like efavirenz, delavirdine is active only against HIV-1.

94.4.2.2.2 Adverse Effects.

Like efavirenz, delavirdine causes potentially serious *rash*. In clinical trials, rash developed in up to 50% of patients; erythema multiforme and Stevens-Johnson syndrome have been reported. If severe rash develops, the drug should be withdrawn. Other common side effects include headache, fatigue, GI intolerance (nausea, vomiting, diarrhea), and elevation of liver enzymes.

94.4.2.2.3 Drug Interactions.

In contrast to efavirenz and nevirapine, which induce cytochrome P450, delavirdine *inhibits* cytochrome P450. As a result, levels of drugs taken concurrently may rise. To avoid toxicity from excessive drug levels, patients should not take cisapride, alprazolam, midazolam, triazolam, lovastatin, or simvastatin—or astemizole or terfenadine, which are no longer available in the United States. Other drugs whose levels may be increased include indinavir,

saquinavir, clarithromycin, dapsone, warfarin, quinidine, ergot alkaloids, PDE5 inhibitors (eg, sildenafil [Viagra]), and the dihydropyridine-type calcium channel blockers; all of these agents should be used with caution.

Agents that induce P450 (eg, St. John's wort, rifampin, rifabutin, phenytoin, phenobarbital, carbamazepine) may decrease levels of delavirdine, and may thereby reduce antiviral effects. Don't use delavirdine with these agents.

Drugs that reduce gastric acidity—antacids, histamine₂ (H₂)-receptor antagonists, proton pump inhibitors, and buffered didanosine formulations—can decrease absorption of delavirdine.

94.4.2.2.4 Preparations, Dosage, and Administration.

Delavirdine [Rescriptor] is available in 100- and 200-mg tablets. The recommended dosage is 400 mg 3 times a day, taken with or without food. Patients who are unable to swallow tablets whole can mix 4 of the 100-mg tablets with water (at least 3 ounces) and swallow the resulting suspension. Acidity enhances absorption. Accordingly, patients with achlorhydria (lack of stomach acid) should administer delavirdine with an acidic beverage (eg, orange juice, cranberry juice).

94.4.2.3 Etravirine

94.4.2.3.1 Actions and Use.

Etravirine [Intelence], approved in 2008, is similar to other NNRTIs in actions and uses. The drug is a non-nucleoside that binds to and inhibits reverse transcriptase, and thereby suppresses HIV replication. Like other NNRTIs, etravirine is active only against HIV-1. The drug does not inhibit human DNA polymerases. Etravirine is indicated for treatment-experienced adults infected with HIV-1 strains resistant to other NNRTIs and other antiretroviral drugs, and must always be combined with other effective agents (to suppress emergence of resistance). In many cases, etravirine is effective against HIV strains resistant to other NNRTIs and to PIs.

94.4.2.3.2 Pharmacokinetics.

Etravirine is administered orally and should be taken following a meal. Why? Because food increases absorption by 50%. In the blood, the drug is 99% protein bound, primarily to albumin. Etravirine is metabolized by cytochrome P450 isozymes (primarily CYP3A4,

CYP2C9, and CYP2C19) and then excreted in the urine and feces. The serum half-life ranges from 20 to 60 hours.

94.4.2.3.3 Adverse Effects.

Etravirine is generally well tolerated. However, like other NNRTIs, etravirine can cause potentially serious *rash*. In clinical trials, mild to moderate rash developed in up to 9% of patients, but the incidence of severe reactions—Stevens-Johnson syndrome and erythema multiforme—was low: less than 1%. If severe rash develops, etravirine should be withdrawn. Other adverse effects include nausea (4.7%), vomiting (2.3%), diarrhea (5.2%), abdominal pain (3%), fatigue (3.3%), headache (2.7%), peripheral neuropathy (2.8%), and hypertension (2.8%).

94.4.2.3.4 Use in Pregnancy and Lactation.

No adequate studies have been conducted in pregnant women. Etravirine is classified in FDA Pregnancy Category B. Mothers should not breast-feed while taking this drug.

94.4.2.3.5 Drug Interactions.

Etravirine is subject to *many* drug interactions. As noted, etravirine is a *substrate* for CYP3A4, CYP2C9, and CYP2C19. In addition, it can *induce* 3A4 and *inhibit* 2C9 and 2C19. Accordingly, the following generalities apply:

- Drugs that inhibit CYP3A4, CYP2C9, or CYP2C19 may raise etravirine levels.
- Drugs that induce CYP3A4, CYP2C9, or CYP2C19 may reduce etravirine levels.
- Etravirine can reduce levels of drugs that are substrates for 3A4.
- Etravirine can raise levels of drugs that are substrates for 2C9 and 2C19.

Some specific interacting drugs are listed in [Table 93-4](#).

94.4.2.3.6 Preparations, Dosage, and Administration.

Etravirine [Intelence] is available in 100-mg tablets. The adult dosage is 200 mg twice daily, taken following a meal.

1099

94.5 PROTEASE INHIBITORS

The protease inhibitors (PIs) are among the most effective antiretroviral drugs available. When used in combination with NRTIs, they can reduce viral load to a level that is undetectable with current assays.

In early trials, PIs were generally well tolerated, although they did cause GI disturbances. However, widespread use of these drugs has revealed additional side effects: fat maldistribution, hyperglycemia and diabetes, reduced bone mineral density, increased bleeding in hemophiliacs, and elevation of triglyceride and transaminase levels.

All of the PIs can inhibit cytochrome P450, and can thereby increase levels of other drugs. Because of this mechanism and others, PIs are subject to a bewildering array of drug interactions.

As with other antiretroviral drugs, HIV resistance can be a significant problem. Mutant strains of HIV that are resistant to one PI are likely to be cross-resistant to other PIs. In contrast, since PIs do not share the same mechanism as the reverse transcriptase inhibitors or fusion inhibitors, cross-resistance between PIs and these other antiretroviral drugs does not occur. To reduce the risk of resistance, PIs should never be used alone; rather, they should always be combined with at least one reverse transcriptase inhibitor, and preferably two.

Ten PIs are available. Unfortunately, data on comparative efficacy of these drugs are limited. Accordingly, until such data become available, selection among them must be based on other factors, mainly side effect profile, drug interactions, and patient acceptance. The major properties of the PIs are summarized in [Tables 93-5](#) and [93-6](#).

94.5.1 Group Properties

94.5.1.1 Adverse Effects

94.5.1.1.1 Hyperglycemia/Diabetes.

Protease inhibitors have been associated with hyperglycemia, new-onset diabetes, abrupt exacerbation of existing diabetes, and diabetic ketoacidosis. Onset typically occurs after 2 months of drug use, but can also develop much earlier. Hyperglycemia can be managed with insulin and oral antidiabetic agents (eg, metformin). Because of the possible risk of diabetes, patients should be instructed to report signs of the disease, such as polydipsia (increased fluid intake), polyphagia (increased food intake), and polyuria. In patients with existing diabetes, blood glucose should be monitored closely. In others, blood glucose should be measured at

baseline, every 3 to 4 months during the first year of treatment, and less frequently thereafter. Although withdrawing PIs may restore normal glucose metabolism, discontinuation is not recommended.

94.5.1.1.2 Fat Maldistribution.

Use of PIs has been associated with maldistribution of body fat, sometimes referred to as *lipodystrophy syndrome* or *pseudo-Cushing's syndrome*. Fat accumulates in the abdomen (“protease paunch”), in the breasts of men and women, and between the shoulder blades (“buffalo hump”). Fat is lost from the face, arms, buttocks, and legs. Leg and arm veins become prominent. Muscle mass and strength are unaffected. The underlying mechanism has not been determined. Although these fat changes resemble those of Cushing's syndrome, which is caused by excessive cortisol, elevated cortisol has not been observed. Health risks of the syndrome are unknown, although it can be psychologically distressing. Drug withdrawal may cause symptoms to resolve, but is not recommended.

In 2004, a product called *Sculptra* was approved for restoring and/or correcting loss of facial fat in people with HIV infection. Sculptra is an injectable form of poly-L-lactic acid, a biodegradable synthetic polymer that has been widely used in dissolvable stitches, bone screws, and facial implants. Administration is by direct injection into the deep dermis or subcutaneous tissue using a 26-gauge needle. After the initial series of injections, repeat treatments may be needed to maintain the correction. Principal adverse effects are local reactions, including redness, swelling, bruising, and development of nodules.

94.5.1.1.3 Hyperlipidemia.

All PIs can elevate plasma levels of cholesterol and triglycerides. These effects may occur with or without redistribution of fat. Elevation of cholesterol can lead to atherosclerosis and associated cardiovascular events. Elevation of triglycerides can lead to pancreatitis. Changes in plasma lipids can be detected by monitoring lipid levels every 3 to 4 months. Potential interventions for hyperlipidemia include diet, exercise, and lipid-lowering drugs. However, benefits of these interventions have not been established. If lipid-lowering drugs are employed, lovastatin and simvastatin should be avoided. Why? Because inhibition of P450 by PIs can cause lovastatin and simvastatin to accumulate to dangerous levels.

94.5.1.1.4 Increased Bleeding in People with Hemophilia.

Protease inhibitors may increase the risk of bleeding in patients with hemophilia. Bleeding typically occurs in the joints and soft tissues, where danger is low. However, serious bleeds

in the brain and GI tract have also occurred. The mean time to increased bleeding is 22 days after the onset of treatment. Patients may need to increase their dosage of coagulation factors.

94.5.1.1.5 Reduced Bone Mineral Density.

Protease inhibitors can accelerate bone loss. In some patients, loss is severe enough to meet the definition of osteoporosis. In a study conducted at Washington University, involving 122 patients on ART, 21% of those taking PIs had osteoporosis. In an Australian study involving 74 patients taking PIs, 28% of patients had low bone mineral density and 10% had osteoporosis. To help protect against bone loss, patients should ensure adequate intake of calcium and vitamin D. If significant bone loss develops, bisphosphonates, raloxifene, calcitonin, or teriparatide may be indicated (see [Chapter 73](#), Drugs Affecting Calcium Levels and Bone Mineralization).

94.5.1.1.6 Elevation of Serum Transaminases.

Protease inhibitors can increase serum levels of transaminases, indicating injury to the liver. Exercise caution in patients with chronic liver disease (eg, hepatitis B or C, cirrhosis). Serum transaminases should be measured at baseline and periodically thereafter.

94.5.1.2 Drug Interactions

All PIs are metabolized by cytochrome P450 enzymes, and all PIs can inhibit cytochrome P450 enzymes. As a result, PIs can interact with drugs that inhibit or induce P450 enzymes, and with drugs that are substrates for P450 enzymes. Drug interactions of the PIs are summarized in [Table 93-6](#).

94.5.1.2.1 P450 Inhibitors.

Agents that inhibit P450 can retard metabolism of the PIs, thereby increasing their levels. Important inhibitors include *ketoconazole* (an antifungal drug), *clarithromycin* (an antibacterial drug), and *grapefruit juice*. If inhibition of metabolism is substantial, dosage of the PI should be reduced.

1100

1101

94.5.1.2.2 P450 Inducers.

Drugs that induce P450 can accelerate the metabolism of PIs, and can thereby reduce their levels. Important inducers include *rifampin* and *rifabutin* (used for mycobacterial infections), and three antiseizure drugs: *phenobarbital*, *phenytoin*, and *carbamazepine*. If induction of

P450 is substantial, loss of therapeutic effects can result. For example, when rifampin is combined with the PI indinavir, total body content of indinavir is reduced by 92%. Similar reductions occur with other PIs. Accordingly, combined use of rifampin and PIs should be avoided.

94.5.1.2.3 P450 Substrates.

By inhibiting P450, PIs can slow the metabolism of other drugs, thereby causing their levels to rise. Serious toxicity can result. To avoid toxicity, PIs should not be combined with the following P450 substrates: *astemizole* and *terfenadine* (nonsedating antihistamines; no longer available in the United States); *cisapride* (a drug for heartburn; available in the United States, but with limited access); *alprazolam*, *triazolam*, and *midazolam* (benzodiazepine sedative-hypnotics); *ergotamine* and *dihydroergotamine* (drugs that promote vasoconstriction and relieve migraine); and *lovastatin* and *simvastatin* (drugs that lower cholesterol).

By inhibiting P450, PIs can intensify and prolong the effects of three PDE5 inhibitors used for erectile dysfunction: *sildenafil* [Viagra], *tadalafil* [Cialis], and *varденаfil* [Levitra]. Although this might seem beneficial, it is potentially dangerous. Accordingly, dosages of these drugs should be reduced: sildenafil should not exceed 25 mg in 48 hours; tadalafil should not exceed 10 mg every 72 hours; and vardenafil should not exceed 2.5 mg in 72 hours.

94.5.1.2.4 Protease Inhibitor Combinations: Ritonavir Boosting.

By inhibiting P450, one PI can increase the level of another PI, and can thereby intensify therapeutic effects (as well as adverse effects). One PI—ritonavir [Norvir]—is routinely combined with other PIs with the specific purpose of increasing the other PIs' effects. As indicated in [Table 93-8 on p. 1114](#), this technique of “ritonavir boosting” is currently used with five PIs: atazanavir, darunavir, fosamprenavir, lopinavir, and saquinavir. In all five combinations, the dose of ritonavir is low: 100 to 400 mg/day. This dosage is too low to contribute significant antiviral effects, but still high enough to inhibit P450.

94.5.1.3 Herb Interactions

94.5.1.3.1 St. John's Wort.

St. John's wort, an herbal supplement taken for depression, can decrease levels of all PIs. The principal mechanism is accelerated metabolism owing to induction of P450 (see [Chapter 107](#)). To avoid loss of efficacy, patients using PIs must not use St. John's wort.

94.5.1.3.2 Garlic.

Garlic supplements can decrease levels of saquinavir, and probably levels of other PIs. Scientists at the National Institutes of Health reported that garlic supplements can produce a dramatic (50%) decrease in blood levels of saquinavir. Not only is this effect profound, it persists: 10 days after stopping garlic intake, saquinavir levels remained 30% to 40% below baseline. These observations are significant. Why? Because many patients with HIV infection take garlic supplements on the belief (albeit unfounded) that garlic can suppress HIV replication and stimulate immune function. Although we don't know how garlic lowers saquinavir levels, induction of P450 is suspected. If this is correct, garlic supplements are likely to reduce levels of other drugs, including other PIs and NNRTIs. Accordingly, it would seem prudent for patients taking PIs or NNRTIs to avoid garlic supplements. The small amount of garlic in prepared foods is probably of no concern.

94.5.2 Lopinavir/Ritonavir

94.5.2.1 Description and Use.

Lopinavir and ritonavir are available in a fixed-dose combination under the trade name *Kaletra*. The combination is approved for HIV infection in adults and children over 6 months old. Lopinavir is the active antiretroviral component. Ritonavir is present only to boost lopinavir's effects: By inhibiting P450, ritonavir raises lopinavir levels substantially, and thereby greatly enhances antiviral actions. The amount of ritonavir, although large enough to inhibit P450, is too small to exert significant antiretroviral effects. Hence, therapeutic responses to the combination are due solely to lopinavir. In clinical trials, lopinavir/ritonavir was highly effective, and even worked against some HIV strains that had become resistant to other PIs. Lopinavir/ritonavir is a preferred component for multidrug antiretroviral regimens.

94.5.2.2 Mechanism of Action.

To understand the effects of lopinavir and the other PIs, we must first understand the function of HIV protease. As discussed above, protease catalyzes the final step in HIV maturation. When the various enzymes and structural proteins of HIV are synthesized, they are not produced as separate entities; rather, they are strung together in large polyproteins. The role of protease is to cleave bonds in the polyproteins, thereby freeing the individual enzymes and structural proteins. Once these components have been freed, HIV can complete its maturation.

Protease inhibitors bind to the active site of HIV protease and thereby prevent the enzyme from cleaving HIV polyproteins. As a result, the structural proteins and enzymes of HIV are unable to function, and hence the virus remains immature and noninfectious.

94.5.2.3 Pharmacokinetics.

Discussion here is limited to lopinavir. The pharmacokinetics of ritonavir are discussed below.

Lopinavir is administered orally, and absorption is enhanced by food. In blood, the drug is highly (99%) bound to plasma proteins. Lopinavir undergoes extensive metabolism by the CYP3A4 isozyme of P450, followed by excretion in the urine (10%) and feces (83%). The drug's half-life is 5 to 6 hours.

Two observations tell us that the antiretroviral effects of lopinavir/ritonavir are due entirely to lopinavir. First, when patients take lopinavir/ritonavir, steady-state levels of lopinavir are 15- to 20-fold *higher* than those of ritonavir. Second, in the test tube, the concentration of lopinavir required to suppress HIV replication is 10-fold *lower* than that of ritonavir. Therefore, since lopinavir achieves much higher concentrations than ritonavir, and yet works at much lower concentrations than ritonavir, it is clear that virtually all of the antiviral effects of the combination are due to lopinavir.

94.5.2.4 Adverse Effects.

Lopinavir/ritonavir is generally well tolerated. The most common adverse effects are diarrhea (13.8%), nausea (6.4%), headache (2.5%), and weakness or tiredness (3.4%). Like all other PIs, lopinavir/ritonavir poses a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminases, and increased bleeding in patients with hemophilia. Rash may occur in children.

94.5.2.5 Drug Interactions.

Lopinavir/ritonavir *inhibits* two drug-metabolizing enzymes—CYP3A4 and CYP2D6—and can thereby raise levels of drugs that are substrates for these enzymes. Serious toxicity can result. To avoid toxicity, certain drugs must be used in greatly reduced dosage, and others must not be used at all. Drugs that require a large reduction in dosage include clarithromycin, ketoconazole, itraconazole, rifabutin, and PDE5 inhibitors used for erectile dysfunction (eg, sildenafil [Viagra]). Drugs that must be avoided entirely include cisapride, flecainide, propafenone, dihydroergotamine, ergonovine, ergotamine, methylergonovine, pimozide,

1101

1104

midazolam, triazolam, lovastatin, and simvastatin—and astemizole and terfenadine, which are no longer available in the United States.

TABLE 93-5 Properties of Protease Inhibitors (PIs)

	Lopinavir/Ritonavir	Ritonavir	Indinavir	Saquinavir	Amprenavir	Fosamprenavir	Nelfinavir	Atazanvir	Darunavir	Tipranavir
Trade Name	Kaletra	Norvir	Crixivan	Invirase	Agenerase	Lexiva	Viracept	Reyataz	Prezista	Aptivus
Formulations	Caps: 133.3 mg lopinavir/33.3 mg ritonavir PO soln: 80 mg/mL lopinavir/20 mg/mL ritonavir	Caps: 100 mg PO soln: 600 mg/7.5 mL	Caps: 100, 200, 333, and 400 mg	Hard-gel caps: 200 mg Tablets: 500 mg	Capsules: 50 mg PO soln: 15 mg/mL Note: Capsules and solution are not interchangeable on a mg-for-mg basis	Tablets: 700 mg Suspension: 50 mg/mL	Tablets: 250 and 625 mg PO powder: 50 mg/gm	Capsules: 100, 150, 200, 300 mg	Tablets: 75, 150, 300, 400, 600, and 750 mg	Capsules: 250 mg
Dosage	400 mg lopinavir/100 mg ritonavir twice daily or 800 mg lopinavir/200 mg ritonavir once daily or When used with efavirenz or nevirapine: 533 mg lopinavir/133 mg ritonavir twice daily	600 mg every 12 hr Separate dosing with buffered didanosine by 2 hr	800 mg every 8 hr, or every 12 hr with ritonavir (100 or 200 mg) Separate dosing with buffered didanosine by 1 hr	Must be used boosted with ritonavir. Dosage is 1000 mg Invirase/100 mg ritonavir twice daily.	<i>Adults:</i> 1400 mg 2 times/day (oral solution) <i>Children:</i> see text	Dosage depends on treatment history, liver function, and use of ritonavir (see text).	750 mg 3 times/day or 1250 mg 2 times/day Dosage for combined use with efavirenz or tenofovir: see text.	400 mg once daily Separate dosing with buffered didanosine by 2 hr Dosage for combined use with efavirenz or tenofovir: see text.	<i>ART-naïve patients:</i> 800 mg once daily, boosted with 100 mg ritonavir once daily <i>ART-experienced patients:</i> 600 mg twice daily, boosted with 100 mg ritonavir twice daily	500 mg twice daily, boosted with 200 mg ritonavir twice daily
Impact of Food	Moderate-fat meal increases absorption from capsules and solution by 48% and 80%, respectively. Take with food.	Food increases levels by 15%. Take with food, if possible, to improve tolerability.	Food decreases levels by 77%. Take 1 hr before meals or 2 hr after; may take with skim milk or a low-fat meal. If boosted with ritonavir, may take without regard to meals.	No food effect when taken with ritonavir	High-fat meals decrease absorption. May take with or without food, but not with a high-fat meal.	Food has little effect on absorption.	Food increases levels 2- to 3-fold. Take with a meal or a snack.	Food increases bioavailability. Take with food. Avoid taking with antacids.	Food increases bioavailability. Take with food.	Bioavailability increased by high-fat meal. Take with food.
Storage	Can store at room temperature up to 2 months; refrigerate for long-term storage	Refrigerate capsules. Do not refrigerate oral solution.	Room temperature, but protect from moisture	Room temperature	Room temperature	Room temperature	Room temperature	Room temperature	Room temperature	Store unopened bottle refrigerated. Open bottle can be kept at room temperature, but must be used in 60 days.
Bioavailability	Not determined	Adequate	65%	Low (4%) and erratic	Not determined	Not determined	20–80% (with ritonavir)	Not determined	82% (with ritonavir)	Not determined
Plasma Half-life	5–6 hr	3–5 hr	1.5–2 hr	1–2 hr	7.1–10.6 hr	7.7 hr	3.5–5 hr	7 hr	15 hr (with ritonavir)	6 hr
Adverse Effects	• Fat maldistribution									
Common to All PIs	<ul style="list-style-type: none"> • Hyperlipidemia • Hyperglycemia—PIs may exacerbate hyperglycemia in patients with existing diabetes, and may cause new-onset diabetes • Possible increased risk of bleeding in patients with hemophilia • Bone loss • Elevation of serum transaminases 									

Adverse Effects of Individual PIs	<ul style="list-style-type: none">• GI: nausea, vomiting, diarrhea (higher incidence with once-daily dosing)• Weakness/tiredness	<ul style="list-style-type: none">• GI: nausea, vomiting, diarrhea<ul style="list-style-type: none">• Paresthesias (circumoral and peripheral)• Asthenia• Taste perversion	<ul style="list-style-type: none">• GI: nausea<ul style="list-style-type: none">• Nephrolithiasis• Indirect hyperbilirubinemia• Miscellaneous: headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia	<ul style="list-style-type: none">• GI: nausea, diarrhea<ul style="list-style-type: none">• Headache	<ul style="list-style-type: none">• GI: nausea, vomiting, diarrhea<ul style="list-style-type: none">• Rash• Oral paresthesias• Propylene glycol toxicity (with the oral solution)	<ul style="list-style-type: none">• GI: nausea, vomiting, diarrhea<ul style="list-style-type: none">• Rash• Headache	<ul style="list-style-type: none">• GI: diarrhea	<ul style="list-style-type: none">• Indirect hyperbilirubinemia<ul style="list-style-type: none">• Prolongs PR interval, posing a risk of atrioventricular block• Use with caution in patients with underlying conduction defects or on concomitant medications that can cause PR prolongation• Nephrolithiasis	<ul style="list-style-type: none">• GI: nausea, diarrhea<ul style="list-style-type: none">• Rash• Headache• Stevens-Johnson syndrome• Hepatotoxicity	<ul style="list-style-type: none">• Hepatotoxicity<ul style="list-style-type: none">• Rash
	Drug interactions for the PIs are summarized in Table 93-6 .									
Drug Interactions										

TABLE 93-6 Drug Interactions of Protease Inhibitors (PIs)

Lopinavir/Ritonavir [Kaletra]	Ritonavir [Norvir]	Indinavir [Crixivan]	Saquinavir [Invirase]	Nelfinavir [Viracept]	Amprenavir [Agenerase]	Fosamprenavir [Lexiva]	Atazanavir [Reyataz]	Darunavir [Prezista]	Tipranavir [Aptivus]
Interactions Shared by All PIs <ul style="list-style-type: none"> All PIs inhibit P450 (ritonavir inhibits the most) and hence can cause other drugs to accumulate to dangerous levels. Accordingly, <i>patients must not take the following drugs</i>: astemizole, terfenadine, cisapride, alprazolam, triazolam, midazolam, ergotamine, dihydroergotamine, lovastatin, and simvastatin. By inhibiting P450, PIs can increase levels of sildenafil [Viagra], tadalafil [Cialis], and vardenafil [Levitra]; dosages of all three should be reduced. St. John's wort induces P450 and thereby decreases levels of PIs. Combined use of St. John's wort and protease inhibitors must be avoided. Certain antiseizure drugs—phenobarbital, phenytoin, and carbamazepine—induce P450, and may thereby decrease levels of PIs substantially. 									
Interactions of Individual PIs									
<ul style="list-style-type: none"> Because of P450 inhibition, <i>patients must avoid the following drugs</i> (in addition to those listed for all PIs): flecainide, propafenone, ergonovine, methylergonovine, and pimozide. Rifampin, efavirenz, and nevirapine greatly reduce levels of lopinavir, and hence should be avoided. Because of P450 inhibition, dosages of the following drugs must be <i>greatly reduced</i>: clarithromycin, ketoconazole, itraconazole, and rifabutin. Lopinavir/ritonavir decreases levels of ethinyl estradiol found in oral contraceptives; use a different form of birth control. Lopinavir/ritonavir decreases methadone availability by 53%; monitor methadone efficacy and increase dose as needed. Owing to its alcohol content, the PO solution of lopinavir/ritonavir should not be combined with disulfiram or metronidazole. 	<ul style="list-style-type: none"> Because of P450 inhibition, <i>patients must avoid the following drugs</i> (in addition to those listed for all PIs): amiodarone, bepridil, bupropion, clonazepam, diazepam, encainide, estazolam, flurazepam, meperidine, piroxicam, propoxyphene, propafenone, quinidine, and zolpidem. Ritonavir decreases levels of ethinyl estradiol found in oral contraceptives; use a different method of birth control. Ritonavir increases levels of rifabutin (4-fold), ketoconazole (3-fold), clarithromycin (77%), and desipramine (145%); reduce dosages of these drugs. Buffered formulations of didanosine reduce ritonavir absorption; take at least 2 hr apart. 	<ul style="list-style-type: none"> Rifampin reduces indinavir levels by 89%; avoid the combination. Indinavir increases rifabutin levels 2-fold; reduce rifabutin dosage. Buffered formulations of didanosine reduce indinavir absorption; take at least 1 hr apart. 	<ul style="list-style-type: none"> Rifampin and rifabutin reduce levels of saquinavir; don't use these drugs. Saquinavir levels are increased by ritonavir, ketoconazole, clarithromycin, and grapefruit juice. 	<ul style="list-style-type: none"> Rifampin reduces nelfinavir levels by 82%; avoid the combination. Rifabutin reduces nelfinavir levels by 32%; increase nelfinavir dosage. Nelfinavir decreases levels of ethinyl estradiol and norethindrone found in oral contraceptives; use a different method of birth control. Nelfinavir increases levels of ketoconazole. 	<ul style="list-style-type: none"> Rifampin reduces amprenavir levels by 90%; avoid the combination. Amprenavir may reduce efficacy of oral contraceptives; use a different method of birth control. Disulfiram and metronidazole increase the risk of toxicity from propylene glycol in amprenavir oral solution; avoid these drugs. Don't take within 1 hr of antacids or buffered didanosine. 	<ul style="list-style-type: none"> Fosamprenavir undergoes conversion to amprenavir in the body, and hence the interactions of fosamprenavir are the same as those listed for amprenavir. Amprenavir increases rifabutin levels by 193%; reduce rifabutin dosage. 	<ul style="list-style-type: none"> Because of P450 inhibition, <i>patients must avoid</i> bepridil and pimozide (in addition to the drugs listed for all PIs). Use clarithromycin, atorvastatin, and diltiazem in reduced dosage, and use cyclosporine, sirolimus, and tacrolimus with caution. Drugs that raise gastric pH can decrease the solubility of atazanavir, and thereby decrease its absorption. Atazanavir should be taken 2 hr before or 1 hr after antacids or buffered medications, and 12 hr apart from H₂-receptor blockers. Proton pump inhibitors should be avoided. Rifampin reduces levels of atazanavir; don't combine these drugs. Atazanavir greatly increases levels of irinotecan (by inhibiting UDP glucuronyltransferase); don't combine these drugs. 	<ul style="list-style-type: none"> Always combine with ritonavir to boost darunavir levels. Rifampin can greatly reduce darunavir levels, and hence should be avoided. Ketoconazole can increase darunavir levels by 42%. Use with caution. Darunavir can reduce levels of two antidepressants: paroxetine and sertraline. Titrate antidepressant dosage based on clinical response. 	<ul style="list-style-type: none"> Tipranavir must be taken with ritonavir (to boost tipranavir levels). Because of P450 inhibition, <i>patients must avoid</i> amiodarone, flecainide, and pimozide (in addition to the drugs listed for all PIs). By inducing P-glycoprotein, tipranavir/ritonavir can greatly decrease levels of amprenavir, fosamprenavir, lopinavir, and saquinavir, and hence should not be used with these other PIs. Tipranavir/ritonavir decreases levels of ethinyl estradiol in oral contraceptives; use a different form of contraception.

Paradoxically, lopinavir/ritonavir can *induce* metabolism of some drugs, including methadone and ethinyl estradiol, a component of many oral contraceptives. Methadone efficacy should be

monitored and dosage increased as needed. Women using ethinyl estradiol-based oral contraceptives should switch to a different form of birth control.

Agents that induce CYP3A4 can accelerate metabolism of lopinavir/ritonavir, and can thereby decrease antiretroviral effects. Known inducers include rifampin, efavirenz, nevirapine, phenobarbital, phenytoin, carbamazepine, and St. John's wort. Concurrent use of these agents should be avoided.

1104

Because of its alcohol content (see below), the oral solution of lopinavir/ritonavir should not be combined with disulfiram [Antabuse] or metronidazole. Why? Because both drugs will cause accumulation of acetaldehyde, a toxic metabolite of alcohol.

1105

94.5.2.6 Preparations, Dosage, and Administration.

Lopinavir/ritonavir [Kaletra] is available in soft-gelatin capsules (133.3 mg lopinavir/33.3 mg ritonavir) and an oral solution (80 mg lopinavir/20 mg ritonavir per milliliter) prepared in 42% alcohol. Dosing should be done with food.

The *adult dosage* for patients not taking efavirenz or nevirapine is either (1) 400 mg/100 mg twice daily or (2) 800 mg/200 mg once daily, but only in treatment-naïve patients. For patients taking efavirenz or nevirapine, the dosage is 533 mg/133 mg twice daily.

Pediatric dosages are based on body weight: For children weighing 7 to 14.9 kg, the dosage of lopinavir/ritonavir is 12/3 mg/kg twice daily; for children weighing 15 to 40 kg, the dosage is 10/2.5 mg/kg twice daily; and for children weighing more than 40 kg, the dosage is the same as for adults.

94.5.3 Other Protease Inhibitors

94.5.3.1 Ritonavir

94.5.3.1.1 Actions and Uses.

Ritonavir [Norvir] inhibits HIV protease, and thereby prevents maturation of HIV. The drug is active against both HIV-1 and HIV-2. Ritonavir is approved for treatment of HIV infection in adults and children. To reduce emergence of resistance, ritonavir should always be combined with at least one reverse transcriptase inhibitor. Because of its ability to inhibit P450, ritonavir is often combined with other PIs to boost their effects.

1105

94.5.3.1.2 Pharmacokinetics.

Ritonavir is well absorbed following administration, either in capsules or oral solution. Food increases absorption of ritonavir in capsules by 15%. Dilution of the oral solution in chocolate milk, Ensure, or Advera has no impact on absorption, but does improve its taste (which is otherwise unpleasant). Ritonavir undergoes metabolism by the hepatic P450 system, followed by excretion in the feces (84%) and urine (11%). The plasma half-life is 3 to 5 hours.

94.5.3.1.3 Adverse Effects.

Adverse effects are common during the initial weeks of therapy and then tend to fade. The effects seen most often are nausea (25%), diarrhea (16%), vomiting (14%), muscle weakness (12%), altered taste (8%), and paresthesias (tingling or numbness) around the mouth and in the extremities. These effects can be reduced by initiating therapy at a low dosage and then gradually titrating up to the maintenance dosage. Like other PIs, ritonavir may pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminase levels, and increased bleeding in patients with hemophilia.

94.5.3.1.4 Drug Interactions.

Ritonavir is a *powerful inhibitor of P450 drugmetabolizing enzymes*, and can thereby decrease the metabolism of other drugs, causing their levels to rise. Because drug accumulation can result in serious adverse effects, ritonavir is contraindicated for use with a large number of agents, including terfenadine and astemizole (no longer available in the United States), which can cause fatal dysrhythmias when present at excessive levels. A complete list of contraindicated drugs is given in [Table 93-6](#).

Although ritonavir inhibits P450, it appears to *induce* other drugmetabolizing enzymes, and can thereby *decrease* levels of certain drugs. Among these are *ethinyl estradiol* (a component of many oral contraceptives), *zidovudine*, *clarithromycin*, *sulfamethoxazole*, and *theophylline*. Care must be taken to ensure that concentrations of these drugs do not fall to subtherapeutic levels.

Ritonavir is often used with other PIs to boost their effects. Benefits derive from inhibiting P450.

St. John's wort induces cytochrome P450, and can thereby decrease levels of ritonavir. Accordingly, the combination should be avoided.

94.5.3.1.5 Preparations, Dosage, and Administration.

94.5.3.1.5.1 Preparations.

Ritonavir [Norvir] is available in 100-mg capsules and an oral solution (600 mg/7.5 mL). In addition, the drug is available in a fixed-dose combination with lopinavir under the trade name Kaletra (see above).

94.5.3.1.5.2 Dosage and Administration.

The maintenance dosage for adults is 600 mg every 12 hours. The maintenance dosage for children is 400 mg/m² every 12 hours. Adverse effects can be minimized by starting therapy with a low dosage and then titrating up to the maintenance dosage. If possible, ritonavir should be administered with food. Palatability of the oral solution can be improved by mixing it with chocolate milk, Ensure, or Advera within 1 hour of administration. Ritonavir should be stored refrigerated (2°C to 8°C; 36°F to 46°F) and protected from light.

94.5.3.2 Indinavir

94.5.3.2.1 Actions and Use.

Indinavir [Crixivan] inhibits HIV protease and thereby prevents the cleavage of large HIV polyproteins into their smaller, functional forms. As a result, HIV particles remain immature and noninfectious. Indinavir is approved only for treatment of HIV infection. To reduce the risk of resistance, indinavir is usually combined with two NRTIs.

94.5.3.2.2 Pharmacokinetics.

When administered on an empty stomach, indinavir has good (65%) bioavailability. Administration with a meal high in fat, protein, or calories can decrease absorption by 70%. Indinavir undergoes metabolism by hepatic P450 followed by excretion in the feces (83%) and urine (19%). The plasma half-life is 1.5 to 2 hours. In patients with liver dysfunction, indinavir levels may increase and the half-life may be prolonged.

94.5.3.2.3 Adverse Effects.

Indinavir is generally well tolerated. The major adverse effect of note is *nephrolithiasis* (kidney stones), manifested by flank pain with or without hematuria. As a rule, indinavir-induced nephrolithiasis does not compromise kidney function, and resolves following hydration and interruption of indinavir for 1 to 3 days. To decrease the risk of nephrolithiasis, patients should consume at least 48 ounces (1.5 L) of water daily. Like other PIs, indinavir may pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminase levels, and increased bleeding in patients with hemophilia. Other side effects include GI intolerance, headache, asthenia (weakness), blurred vision, dizziness, rash, metallic taste, thrombocytopenia, and indirect hyperbilirubinemia.

94.5.3.2.4 Drug Interactions.

Indinavir *inhibits cytochrome P450*, and can thereby decrease the metabolism of other drugs. As a result, drugs may accumulate to dangerous or even life-threatening levels. Agents that can produce serious toxicity because of this interaction include *cisapride*, *alprazolam*, *triazolam*, *midazolam*, *ergot alkaloids*, *simvastatin*, and *lovastatin*—as well as *astemizole* and *terfenadine*, which are no longer available in the United States. Accordingly, patients taking indinavir must not be given these drugs.

Buffered formulations of didanosine can decrease absorption of indinavir. The mechanism is reduction of acidity. Let me explain. Didanosine and indinavir differ in their acidity requirements: whereas indinavir needs acidity for absorption, acidity decreases absorption of didanosine. Because acidity decreases absorption of didanosine, some formulations contain a buffering agent to neutralize gastric acid (other formulations are enteric coated). Hence, if buffered didanosine and indinavir are administered together, the buffering agent in didanosine will reduce absorption of indinavir. To prevent this interaction, indinavir and buffered didanosine should be administered at least 1 hour apart.

Rifampin, *rifabutin*, and *St. John's wort* can induce cytochrome P450. As a result, these agents can accelerate metabolism of indinavir, thereby decreasing its levels. In contrast, levels of indinavir can be increased by *ketoconazole*, a drug that inhibits P450.

94.5.3.2.5 Preparations, Dosage, Administration, and Storage.

Indinavir [Crixivan] is available in capsules (100, 200, 333, and 400 mg) for oral administration. The recommended dosage is 800 mg every 8 hours (or 800 mg every 12 hours with a 100-mg ritonavir boost). To maximize absorption, administer the drug either (1) with water but on an empty stomach (ie, 1 hour before a meal or 2 hours after); or (2) with skim milk, coffee, tea, or a low-fat meal (eg, corn flakes with skim milk and sugar). Do not administer with a large meal. If the regimen includes buffered didanosine, indinavir and didanosine should be administered at least 1 hour apart.

Indinavir should be stored at room temperature and protected from moisture, which can degrade the drug. To protect indinavir from moisture, store tightly sealed in the vesicant-containing package supplied by the manufacturer.

94.5.3.3 Saquinavir

Saquinavir was the first PI to receive Food and Drug Administration (FDA) approval. In the test tube, the drug appears more potent than other PIs.

94.5.3.3.1 Formulations.

Saquinavir is available in two formulations: *tablets* and *hard-gelatin capsules*, both sold under the trade name *Invirase*. A third formulation—soft-gelatin capsules sold as *Fortovase*—has been voluntarily withdrawn. To ensure adequate saquinavir levels, Invirase tablets and capsules must be boosted with ritonavir.

94.5.3.3.2 Actions and Therapeutic Use.

Saquinavir inhibits HIV protease and thereby prevents the cleavage of large HIV polyproteins into their smaller, functional forms. As a result, HIV particles remain immature and noninfectious. The drug is approved only for HIV infection. To reduce emergence of resistance, it should always be combined with at least one inhibitor of reverse transcriptase.

94.5.3.3.3 Pharmacokinetics.

Saquinavir is administered orally, always in combination with ritonavir. With this combination, food has no effect on plasma levels. Saquinavir undergoes metabolism by P450 enzymes, followed by excretion in the feces. The plasma half-life is 1 to 2 hours.

94.5.3.3.4 Adverse Effects.

Saquinavir is generally well tolerated. The most common side effects are GI reactions: nausea, diarrhea, dyspepsia, and abdominal pain. As discussed above, saquinavir and all other PIs may pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminase levels, and increased bleeding in patients with hemophilia.

94.5.3.3.5 Drug and Food Interactions.

Agents that *inhibit* P450 (eg, ketoconazole, clarithromycin, grapefruit juice) can raise levels of saquinavir. Conversely, agents that *induce* P450 (eg, rifampin, rifabutin, phenobarbital, St. John's wort) can reduce levels of saquinavir.

Because saquinavir inhibits P450, it can raise levels of other drugs. To avoid toxicity from excessive levels, saquinavir should not be combined with cisapride, alprazolam, triazolam, midazolam, bepridil, ergot alkaloids, simvastatin, and lovastatin—or with astemizole or terfenadine, which are no longer available in the United States.

94.5.3.3.6 Preparations, Dosage, and Administration.

Saquinavir [Invirase] is available in 500-mg tablets and 200-mg hard-gelatin capsules. Both formulations must be boosted with ritonavir. The dosage is 1000 mg saquinavir/100 mg ritonavir taken twice daily, with or without food.

94.5.3.4 Nelfinavir

94.5.3.4.1 Actions and Uses.

Nelfinavir [Viracept] inhibits HIV protease, and thereby prevents maturation of HIV. The drug is approved for treatment of HIV infection in adults and in children as young as 2 years old. To reduce emergence of resistance, nelfinavir should always be combined with at least one reverse transcriptase inhibitor.

1106

94.5.3.4.2 Pharmacokinetics.

Nelfinavir is administered orally, and food increases absorption greatly (two- to threefold). In blood, more than 98% of the drug is protein bound. Nelfinavir undergoes extensive

1107

hepatic metabolism followed by excretion in the feces. Only 1% of the drug is excreted in the urine. The plasma half-life of nelfinavir is 3.5 to 5 hours.

94.5.3.4.3 Adverse Effects.

Diarrhea can be dose limiting. During clinical trials, 20% to 32% of patients developed moderate to severe diarrhea. In most cases, diarrhea can be managed with an over-the-counter antidiarrheal drug (eg, loperamide).

Like other PIs, nelfinavir may pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminase levels, and increased bleeding in patients with hemophilia.

94.5.3.4.4 Drug Interactions.

Like all other PIs, nelfinavir *inhibits P450*, and can thereby decrease the metabolism of other drugs, causing their levels to rise. Accumulation of several drugs, including *astemizole* and *terfenadine* (no longer available in the United States), *cisapride*, *midazolam*, and *ergot alkaloids*, can result in serious adverse effects. Accordingly, these agents are contraindicated for patients taking nelfinavir.

Like ritonavir, nelfinavir can *decrease* levels of *ethinyl estradiol* and *norethindrone*, a combination found in many oral contraceptives. Women taking oral contraceptives should be advised to use an alternative or additional form of contraception.

Rifampin, *rifabutin*, and *St. John's wort* induce hepatic drug-metabolizing enzymes, and can thereby decrease levels of nelfinavir. Accordingly, patients receiving nelfinavir should avoid these agents.

94.5.3.4.5 Preparations, Dosage, and Administration.

Nelfinavir [Viracept] is available in tablets (250 and 625 mg) and a powder (50 mg/gm) for oral administration. The powder should be mixed with a small amount of water, milk, formula, soy formula, soy milk, or dietary supplement—but *not* with acidic foods or juices (eg, applesauce, apple juice, orange juice) because the resulting combination may have a bitter taste. The recommended adult dosage is 750 mg every 8 hours or 1250 mg every 12 hours. The pediatric dosage is 20 to 30 mg/kg every 8 hours. Nelfinavir should be administered with food to enhance absorption.

94.5.3.5 Amprenavir

94.5.3.5.1 Actions and Use.

Amprenavir [Agenerase] inhibits HIV protease, and thereby prevents maturation of HIV. The drug is approved for use in combination with other antiretroviral agents for treating HIV-infected adults and children over 4 years old.

94.5.3.5.2 Pharmacokinetics.

Amprenavir is rapidly absorbed following oral administration. High-fat meals reduce absorption and should be avoided. Otherwise, food has no effect on drug levels. Amprenavir has a relatively long half-life (7.1 to 10.6 hours), which permits dosing just 2 times a day. The drug undergoes metabolism by hepatic P450 followed by excretion in the urine (14%) and feces (75%).

Amprenavir is available in two formulations: capsules and oral solution. Bioavailability with the oral solution is lower than with the capsules. Accordingly, dosage must be increased when using the solution.

94.5.3.5.3 Adverse Effects.

The most common adverse effects are nausea (73%), vomiting (29%), perioral paresthesias (26%), rash (25%), mood disorders (15%), and altered taste (10%). Rash is generally mild or moderate, and does not preclude continuing therapy. Rarely, severe rash develops, including potentially fatal Stevens-Johnson syndrome. Like other PIs, amprenavir may pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminase levels, and increased bleeding in patients with hemophilia.

Amprenavir *oral solution* contains a large amount of *propylene glycol*, which can be toxic. Under normal conditions, propylene glycol is converted to a harmless metabolite by alcohol dehydrogenase. However, in patients who cannot metabolize the compound fast enough, propylene glycol can accumulate to toxic levels, causing stupor, seizures, tachycardia, hyperosmolality, lactic acidosis, renal toxicity, and hemolysis. Because of the risk of propylene glycol accumulation, *amprenavir oral solution is contraindicated for pregnant women, children under 4 years old, patients with renal or hepatic failure, and patients taking disulfiram or metronidazole*. Alcohol consumption may also pose a risk.

Amprenavir is a chemical relative of the sulfonamide antibiotics. At this time, we do not know if people with sulfonamide hypersensitivity will also experience hypersensitivity to amprenavir. Until more is known, amprenavir should be avoided in patients with a history of sulfonamide reactions.

94.5.3.5.4 Drug Interactions.

Like all other PIs, amprenavir *inhibits P450*, and can thereby cause other drugs to accumulate to dangerous levels. Accordingly, patients must not be given the following agents: astemizole and terfenadine (no longer available in the United States) or cisapride, alprazolam, triazolam, midazolam, bepridil, ergot alkaloids, simvastatin, and lovastatin.

Rifampin reduces amprenavir levels by 90%. The combination should be avoided.

St. John's wort induces P450, and can thereby reduce amprenavir levels. The combination should be avoided.

Like ritonavir and nelfinavir, amprenavir may reduce the efficacy of *oral contraceptives*. An alternative form of contraception should be used.

To enhance stability, amprenavir formulations contain a large amount of *vitamin E*—much more than the recommended daily allowance. Accordingly, patients should be warned against taking vitamin E supplements.

Patients taking amprenavir oral solution must not take metronidazole or disulfiram, and probably should avoid alcohol.

94.5.3.5.5 Preparations, Dosage, and Administration.

Amprenavir [Agenerase] is available in 50-mg capsules and an oral solution (15 mg/mL). Dosages for the capsules and oral solution are not interchangeable. At least 1 hour should separate administration of amprenavir and administration of antacids or buffered formulations of didanosine.

Because propylene glycol in the oral solution can be harmful, this formulation should be reserved for patients who cannot swallow amprenavir capsules, and cannot use a different PI. The oral solution is contraindicated for pregnant women, children under 4 years old, patients with renal or hepatic failure, and patients taking disulfiram or metronidazole.

94.5.3.5.5.1 Adult Dosage.

The adult dosage is 1400 mg of the oral solution twice daily.

94.5.3.5.5.2 Pediatric Dosage: Capsules.

For children 13 to 16 years old who weigh more than 50 kg, the dosage is 1200 mg twice daily. For children 13 to 16 years old who weigh less than 50 kg, and for children 4 to 12 years old, the dosage is 20 mg/kg twice daily or 15 mg/kg 3 times a day—up to a maximum of 2400 mg/day.

94.5.3.5.5.3 Pediatric Dosage: Oral Solution.

For children 13 to 16 years old who weigh less than 50 kg, and for children 4 to 12 years old, the dosage is 22.5 mg/kg twice daily or 17 mg/kg 3 times a day—up to a maximum of 2800 mg/day.

94.5.3.6 Fosamprenavir

94.5.3.6.1 Basic and Clinical Pharmacology.

Fosamprenavir [Lexiva] is a prodrug that undergoes rapid conversion to amprenavir by enzymes in the GI epithelium during absorption. Accordingly, fosamprenavir is nearly identical to amprenavir with regard to actions, uses, adverse effects, drug interactions, precautions, and contraindications. However, there are a few differences that make fosamprenavir more attractive. The most important is that fosamprenavir is better tolerated: the incidence of nausea and vomiting is much lower with fosamprenavir (about 5% vs. 73%), as is the incidence of skin rash (8% vs. 25%). Of less importance, fosamprenavir may be taken without regard to meals (whereas amprenavir should not be taken with high-fat meals).

94.5.3.6.2 Preparations, Dosage, and Administration.

Fosamprenavir [Lexiva] is available in 700-mg tablets and a 50 mg/mL suspension for oral dosing with or without food. Dosage depends on treatment history, liver function, and concurrent use of ritonavir (a drug that inhibits amprenavir metabolism). Specific dosages are as follows:

Patients who are treatment naive

- 1400 mg twice daily *or*
- 1400 mg once daily plus 200 mg ritonavir once daily *or*
- 700 mg twice daily plus 100 mg ritonavir twice daily

Patients who have used PIs before

- 700 mg twice daily plus 100 mg ritonavir twice daily

Patients with hepatic impairment

- If hepatic impairment is mild to moderate, use with caution at a dosage of 700 mg twice daily, and don't combine with ritonavir.
- If hepatic impairment is more severe, do not use fosamprenavir.

94.5.3.7 Atazanavir

94.5.3.7.1 Actions and Uses.

Atazanavir [Reyataz] inhibits HIV protease and thereby prevents maturation of HIV. The drug is approved for combination use with other antiretroviral agents to treat HIV-infected patients. Dosing is done just once a day. In treatment-experienced patients, atazanavir should be boosted with ritonavir.

1107

94.5.3.7.2 Pharmacokinetics.

1108

Atazanavir is taken orally, and plasma levels peak 2.5 hours after dosing. Food increases the amount absorbed, and decreases absorption variability. Atazanavir undergoes extensive hepatic metabolism, mainly by CYP3A enzymes, followed by excretion in the feces (79%) and urine (13%). Hepatic impairment increases blood levels of atazanavir, and slows elimination. The half-life is 6.4 hours in patients with normal liver function, and increases to 12 hours in those with significant impairment.

94.5.3.7.3 Adverse Effects.

The most common adverse effects are nausea, infection, headache, vomiting, diarrhea, drowsiness, insomnia, and fever. Like other PIs, atazanavir may cause hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, and increased bleeding in patients with

hemophilia. Atazanavir causes less hyperlipidemia than other PIs, but we don't yet know if long-term use will cause less lipodystrophy.

Atazanavir prolongs the PR interval on the electrocardiogram, causing asymptomatic first-degree atrioventricular (AV) block in 5% to 9% of patients. Accordingly, the drug should be used with caution in patients with pre-existing cardiac conduction disturbances, such as marked first-degree AV block, or second- or third-degree AV block.

Atazanavir interferes with normal processing of bilirubin, and thereby raises levels of unconjugated bilirubin in plasma (indirect hyperbilirubinemia). As a result, about 11% of patients develop jaundice (yellowing of the skin) and scleral icterus (yellowing of the eyes), which reverse following drug withdrawal.

94.5.3.7.4

Drug Interactions.

Atazanavir is subject to numerous interactions with other drugs. It can raise levels of other drugs, and other drugs can raise or lower levels of atazanavir.

Because atazanavir is a substrate for CYP3A, drugs that inhibit CYP3A can raise atazanavir levels, and drugs that induce CYP3A can lower atazanavir levels.

St. John's wort, which induces P450, can lower atazanavir levels, thereby posing a risk of therapeutic failure. Accordingly, the combination must be avoided.

Atazanavir inhibits CYP3A4, and can thereby intensify and prolong the effects of many drugs. Toxicity can result. Because of toxicity concerns, certain drugs are contraindicated for use with atazanavir. Among these are ergotamine, ergonovine, methylergonovine, bepridil, cisapride, lovastatin, simvastatin, midazolam, triazolam, and pimozide—as well as astemizole and terfenadine, which are no longer available in the United States. Inhibitors of PDE5—sildenafil, vardenafil, and tadalafil—should be used in reduced dosage, and certain immunosuppressants—cyclosporine, sirolimus, and tacrolimus—should be used with caution. Atazanavir can also inhibit the metabolism of irinotecan; combined use should be avoided.

Drugs that raise gastric pH—antacids, buffered medications, H₂-receptor blockers, and proton pump inhibitors—can decrease the solubility of atazanavir, and can thereby decrease its absorption. Atazanavir should be taken 2 hours before or 1 hour after antacids or buffered medications, and should be taken 12 hours apart from H₂-receptor blockers. Atazanavir should not be used with proton pump inhibitors.

Atazanavir has the potential to interact with many additional drugs, including antidysrhythmics (amiodarone, lidocaine, quinidine), calcium channel blockers (diltiazem, verapamil, felodipine, nifedipine, nifedipine, nicardipine), other PIs (efavirenz, saquinavir, ritonavir), warfarin, rifabutin, clarithromycin, tricyclic antidepressants, and oral contraceptives. Details can be found in product literature.

94.5.3.7.5 Preparations, Dosage, and Administration.

Atazanavir [Reyataz] is supplied in capsules (100, 150, and 200 mg).

Dosage for treatment-naïve adults is 400 mg once daily with food.

Dosage for treatment-experienced adults taking tenofovir (300 mg) or efavirenz (600 mg) is atazanavir (300 mg) plus ritonavir (100 mg). All three drugs—atazanavir, ritonavir, plus tenofovir or efavirenz—should be taken together, once daily, with food. Combining atazanavir with PIs other than tenofovir or efavirenz is not recommended.

If atazanavir is combined with a buffered formulation of didanosine, atazanavir should be taken 2 hours before didanosine or 1 hour after.

In patients with moderate hepatic insufficiency, a reduction in atazanavir dosage should be considered (eg, to 300 mg once daily). In patients with severe hepatic insufficiency, atazanavir should not be used.

94.5.3.8 Tipranavir (Plus Ritonavir)

94.5.3.8.1 Therapeutic Use.

Tipranavir [Aptivus], boosted with ritonavir, is indicated for use with other antiretroviral drugs to treat HIV-infected adults who have evidence of ongoing viral replication and who either (1) have taken antiretroviral drugs for a long time or (2) are infected with HIV strains known to be resistant to multiple PIs. Tipranavir should not be used without ritonavir boosting.

94.5.3.8.2 Mechanism of Action.

Tipranavir inhibits HIV protease, and thereby prevents maturation of HIV. However, in contrast to all other PIs, which are rigid peptides, tipranavir is a flexible nonpeptide. Because of its flexibility, tipranavir can adapt to conformational changes in HIV protease that render

the enzyme resistant to other PIs. As a result, HIV strains that have become resistant to other PIs can still be suppressed with tipranavir.

94.5.3.8.3 Pharmacokinetics.

Absorption from the GI tract is limited, but can be enhanced by a high-fat meal. In the blood, tipranavir is extensively protein bound (more than 99.9%). Tipranavir is a substrate for CYP3A4. However, when the drug is coadministered with ritonavir, conversion to metabolites is minimal. As a result, tipranavir is excreted largely unchanged, primarily in the feces. The plasma half-life is 5 to 6 hours.

94.5.3.8.4 Adverse Effects.

94.5.3.8.4.1 Hepatotoxicity.

Liver damage is the greatest concern. Tipranavir may cause severe hepatitis. Some patients have died. To reduce risk, liver function should be assessed at baseline and frequently thereafter. Patients with chronic hepatitis B or C are especially vulnerable, and hence should be followed closely.

94.5.3.8.4.2 Intracranial Hemorrhage.

There have been reports of fatal and nonfatal cranial hemorrhage. However, a causal relationship has not been established.

94.5.3.8.4.3 Other Adverse Effects.

The most common adverse effects are nausea, vomiting, diarrhea, headache, and fatigue. Tipranavir contains a sulfonamide group, and hence should be used with caution in patients allergic to sulfonamides. Like other PIs, tipranavir may pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, and increased bleeding in patients with hemophilia. Increases in plasma cholesterol and triglycerides with tipranavir are larger than with other PIs.

94.5.3.8.5 Drug Interactions.

Tipranavir/ritonavir is subject to numerous drug interactions. The combination can inhibit the metabolism of some drugs and accelerate the excretion of others. Also, other drugs can alter the kinetics of tipranavir.

The tipranavir/ritonavir combination is a net *inhibitor of CYP3A and CYP2D6*, and hence can intensify the effects of drugs metabolized by these enzymes. To avoid toxicity, patients using tipranavir/ritonavir should not take amiodarone, flecainide, pimozide, midazolam, triazolam, simvastatin, lovastatin, or ergot alkaloids. Dosages of other substrates for CYP3A or CYP2D6 may need a reduction.

The tipranavir/ritonavir combination is a net *inducer of P-glycoprotein*, a transport molecule that pumps drugs into the bile, urine, and gut. Hence, by inducing P-glycoprotein, the combination can hasten the excretion of certain drugs. In particular, tipranavir/ritonavir can greatly decrease levels of amprenavir, lopinavir, and saquinavir, and therefore should not be combined with these PIs. Whether tipranavir/ritonavir decreases levels of other PIs has not been determined.

Tipranavir itself is a substrate for CYP3A and P-glycoprotein. Accordingly, agents such as rifampin and St. John's wort, which induce these pathways, can decrease tipranavir levels, and might thereby cause treatment failure.

94.5.3.8.6 Preparations, Dosage, and Administration.

Tipranavir [Aptivus] is supplied in 250-mg, soft-gelatin capsules. The dosage is 500 mg tipranavir (plus 200 mg ritonavir) taken twice daily with food. Unopened bottles should be refrigerated (2°C to 8°C; 36°F to 46°F). After opening, bottles may be kept at room temperature (25°C; 77°F), but capsules must be used within 60 days.

94.5.3.9 Darunavir (plus Ritonavir)

Darunavir [Prezista], approved in 2006, is a second-generation PI with activity against HIV strains that are resistant to other PIs. Strains resistant to darunavir are generally cross-resistant with all other PIs, except possibly tipranavir. Darunavir, boosted with ritonavir (and combined with other antiretroviral drugs), is used in treatment-experienced adults to manage infection with HIV strains that are resistant to one or more other PIs.

Darunavir is administered PO, and should be taken with food to increase absorption. In blood, the drug is highly (95%) protein bound. When taken alone, darunavir is rapidly inactivated in the liver, primarily by CYP3A. Accordingly, it should always be combined with ritonavir, a PI that inhibits CYP3A. In one study, ritonavir increased darunavir levels 14-fold. When darunavir is combined with ritonavir, its half-life is 15 hours.

Adverse effects are similar to those of other PIs. The most common reactions are diarrhea, nausea, and headache. The incidence of rash is 7%. Some patients experience elevations in serum lipids and aminotransferase activity. Like tipranavir and fosamprenavir, darunavir has a sulfonamide component, and hence should be used with caution in patients with sulfonamide allergy. Of note, signs of glucose dysregulation—new-onset diabetes, worsening of existing diabetes, and hyperglycemia—that occur with other PIs have not been reported with darunavir.

Both darunavir and ritonavir inhibit CYP3A, and hence will increase levels of drugs that depend on CYP3A for their clearance. Because elevated levels of certain drugs can be especially dangerous, they are contraindicated for use with darunavir/ritonavir. In this group are ergot derivatives (ergonovine, ergotamine, dihydroergotamine, methylergonovine), two benzodiazepines (midazolam and triazolam), cisapride (a GI motility agent), and pimozide (a neuroleptic).

1108

1109

Darunavir [Prezista] is available in film-coated tablets (75, 150, 300, 400, 600, and 750 mg). The usual adult dosage is 600 mg (two 300-mg tablets or one 600-mg tablet) taken twice daily with ritonavir (100 mg) and food.

94.6 RALTEGRAVIR, AN INTEGRASE INHIBITOR

94.6.1 Actions and Use.

Raltegravir [Isentress], approved in 2007, is the first and only member of a new class of antiretroviral drugs: the *HIV integrase strand transfer inhibitors*, or simply *integrase inhibitors*. As discussed above, integrase is one of three viral enzymes needed for HIV replication. The other two enzymes—reverse transcriptase and protease—are inhibited by older drugs. As its name implies, integrase inserts HIV genetic material into the DNA of CD4 cells. By inhibiting integrase, raltegravir prevents insertion of HIV DNA, and thereby stops HIV replication. Raltegravir is active against HIV strains resistant to other drugs. At this time, raltegravir is indicated only for combined use with other antiretroviral agents in treatment-experienced adults infected with HIV-1 strains resistant to multiple agents. Another integrase inhibitor—*elvitegravir*—is in the advanced stages of development.

94.6.2 Pharmacokinetics.

Raltegravir is administered orally, and plasma levels peak about 3 hours after dosing. In the blood, about 83% is protein bound. The drug is metabolized by an enzyme known as uridine

diphosphate glucuronosyltransferase (UGT). Metabolites are excreted in the feces and urine. The serum half-life is approximately 9 hours.

94.6.3 Adverse Effects.

Raltegravir is well tolerated. The most common side effects are diarrhea, nausea, fatigue, headache, and itching. However, the incidence was no greater than with placebo. In clinical trials, some patients experienced myopathy and rhabdomyolysis, but a causal relationship has not been established.

94.6.4 Use During Pregnancy and Lactation.

Raltegravir is classified in FDA Pregnancy Category C. No adequate or well-controlled studies have been done in pregnant women. Breast-feeding is not recommended.

94.6.5 Drug Interactions.

Atazanavir and other inhibitors of UGT can increase levels of raltegravir. Conversely, rifampin and other inducers of UGT can lower raltegravir levels.

94.6.6 Preparations, Dosage, and Administration.

Raltegravir [Isentress] is supplied in 400-mg tablets for oral dosing, with or without food. The recommended dosage is 400 mg twice daily. The drug can be stored at room temperature.

94.7 ENFUVIRTIDE, AN HIV FUSION INHIBITOR

Enfuvirtide [Fuzeon], widely known as T-20, is the first and only HIV fusion inhibitor. Unlike most other drugs for HIV, which inhibit essential viral enzymes—either reverse transcriptase, integrase, or protease—enfuvirtide blocks entry of HIV into CD4 T cells. Unfortunately, although enfuvirtide is effective, it is also inconvenient (treatment requires twice-daily subQ injections) and very expensive (treatment costs about \$20,000 a year). Furthermore, injection-site reactions occur in nearly all patients. Significant interactions with other drugs have not been observed. Enfuvirtide received FDA approval in 2003.

94.7.1 Chemistry

Enfuvirtide is a synthetic peptide that contains 36 amino acids. Its molecular weight is 4492. Laboratory synthesis of enfuvirtide is complex: 106 steps are involved, compared with 8 to 12

steps for traditional antiretroviral drugs. As a result, enfuvirtide is expensive to make, which largely explains its high cost.

94.7.2 Mechanism of Action

Enfuvirtide prevents the HIV envelope from fusing with the cell membrane of CD4 cells ([Fig. 93-2](#), step 2), and thereby blocks viral entry and replication. Fusion inhibition results from binding of enfuvirtide to gp41, a subunit of the glycoproteins embedded in the HIV envelope (see [Fig. 93-1](#)). As a result of enfuvirtide binding, the glycoprotein becomes rigid, and hence cannot undergo the configurational change needed to permit fusion of HIV with the cell membrane.

94.7.3 Resistance

Resistance to enfuvirtide has developed in cultured cells and in patients. The cause is a structural change in gp41. In clinical trials, reductions in drug susceptibility have ranged from 4- to 422-fold. Fortunately, the HIV mutations that confer resistance to enfuvirtide do not confer cross-resistance to NRTIs, NNRTIs, or PIs. Conversely, resistance to NRTIs, NNRTIs, or PIs does not confer cross-resistance to enfuvirtide.

The rate at which resistance develops depends on the efficacy of the drugs used concurrently. When the patient's other antiretroviral drugs are still effective, resistance to enfuvirtide develops relatively slowly. However, when there is significant resistance to the other drugs, resistance to enfuvirtide develops rapidly.

94.7.4 Pharmacokinetics

Enfuvirtide is administered subQ, and plasma levels peak in 3 to 12 hours. Bioavailability is about 84%, regardless of the site of injection (upper arm, thigh, abdomen). In the blood, enfuvirtide is 92% protein bound, mainly to albumin. Because enfuvirtide is a peptide, we presume it undergoes breakdown to its constituent amino acids—although studies to identify specific metabolic pathways have not been conducted. The elimination half-life is 3.8 hours.

94.7.5 Therapeutic Use

Enfuvirtide is reserved for treating HIV-1 infection that has become resistant to other antiretroviral agents. Specifically, the drug is indicated for HIV-1 infection in adults and in children 6 years of age and older who are treatment experienced and who have evidence of HIV replication despite ongoing antiretroviral therapy. To delay emergence of resistance, enfuvirtide should always be combined with other antiretroviral drugs.

In clinical trials, enfuvirtide was given to patients with measurable plasma HIV RNA despite use of an optimized antiretroviral regimen (OAR). The result? Compared with patients receiving the OAR alone, those receiving the OAR plus enfuvirtide showed a significant reduction in plasma HIV RNA and an increase in circulating CD4 T cells. Benefits were sustained for at least 24 weeks.

94.7.6 Adverse Effects

94.7.6.1 Injection-Site Reactions.

In clinical trials, injection-site reactions (ISRs) developed in 98% of patients, usually within the first week of treatment. Principal manifestations are pain and tenderness (95%), erythema and induration (89%), nodules or cysts (76%), pruritus (62%), and ecchymosis (small hemorrhagic spots; 48%). Although generally mild to moderate, symptoms can also be severe.

1109

1110

In 17% of patients, individual ISRs persisted more than 7 days. Because ISRs are both common and long lasting, 23% of patients had six or more ongoing ISRs at any given time. The intensity of ISRs can be reduced by rotating the injection site, avoiding sites with an active ISR, and avoiding unnecessarily deep injections. If a severe ISR occurs, or if local infection develops, patients should seek immediate medical attention.

94.7.6.2 Pneumonia.

Enfuvirtide appears to increase the risk of bacterial pneumonia. Patients should be informed about signs of pneumonia (cough, fever, breathing difficulties), and instructed to report them immediately. Enfuvirtide should be used with caution in patients who have pneumonia risk factors: low initial CD4 cell counts, high initial viral load, IV drug use, smoking, and a history of lung disease.

94.7.6.3 Hypersensitivity Reactions.

Because enfuvirtide is a foreign peptide, it can trigger hypersensitivity reactions. Typical symptoms, which may occur individually and in combination, are rash, fever, nausea, vomiting, chills, rigors, hypotension, and elevated serum transaminases. Enfuvirtide has also been associated with respiratory distress, glomerulonephritis, Guillain-Barré syndrome, and primary immune complex reaction, all of which may be immune mediated. If a systemic hypersensitivity reaction occurs, enfuvirtide should be discontinued immediately and never used again.

94.7.6.4 Effects During Pregnancy and Lactation.

In animal studies, enfuvirtide failed to cause fetal harm. Studies in pregnant humans have not been conducted. Until more is known, the drug should be used during pregnancy only if clearly indicated. Enfuvirtide is classified in FDA Pregnancy Risk Category B.

Women with HIV infection should not breast-feed, owing to the risk of HIV transmission. Whether enfuvirtide enters breast milk is unknown.

94.7.7 Drug Interactions

Enfuvirtide appears devoid of significant drug interactions. There are no interactions with other antiretroviral drugs that would require a dosage adjustment for either enfuvirtide or the other agent.

94.7.8 Preparations, Dosage, Administration, and Storage

94.7.8.1 Preparations and Storage.

Enfuvirtide [Fuzeon] is supplied in single-use vials that contain 108 mg of powdered drug, which must be reconstituted to a 90-mg/mL solution by adding 1.1 mL of sterile water for injection. The solution can be used immediately or stored cold (2°C to 8°C; 36°F to 46°F) for up to 24 hours. Before injection, stored solutions should be brought to room temperature and inspected to ensure they are still clear, colorless, and free of bubbles and particulate matter. Powdered enfuvirtide can be stored at room temperature.

94.7.8.2 Dosage and Administration.

The dosage for *adults* is 90 mg (1 mL) injected subQ twice a day. The dosage for *children ages 6 through 12 years* is 2 mg/kg (but not more than 90 mg total) injected subQ twice a day. Injections are made into the upper arm, anterior thigh, or abdomen (but not the navel), using aseptic technique to avoid infection. The site should be moved for each injection. Injections should not be made into tissue that is scarred or bruised, or into sites where there is an ongoing reaction to a previous dose.

94.8 MARAVIROC, A CCR5 ANTAGONIST

94.8.1 Actions.

Maraviroc [Selzentry], approved in 2007, is the first representative of a new class of antiretroviral drugs: the *chemokine receptor 5 (CCR5) antagonists*. As discussed above, CCR5 is a co-receptor that some strains of HIV must bind with in order to enter CD4 cells. Maraviroc binds with CCR5, and thereby blocks viral entry. HIV strains that require CCR5 for entry are referred to as being *CCR5 tropic*. Between 50% and 60% of patients are infected with this type of HIV. Maraviroc and enfuvirtide (a fusion inhibitor) are the only antiretroviral drugs that block HIV entry. All other agents inhibit HIV enzymes, either reverse transcriptase, integrase, or protease.

94.8.2 Therapeutic Use.

Maraviroc is indicated only for combined use with other antiretroviral agents in treatment-experienced adults infected with CCR5-tropic HIV-1 strains that are resistant to multiple drugs. Before treatment, a test must be done to confirm that the infecting strain is indeed CCR5 tropic.

94.8.3 Pharmacokinetics.

Maraviroc is administered PO, and plasma levels peak in 0.5 to 4 hours. With a 300-mg dose, bioavailability is 33%. In the blood, the drug is 70% protein bound. Maraviroc undergoes hepatic conversion to inactive metabolites, primarily by CYP3A4. The serum half-life is 14 to 18 hours.

94.8.4 Adverse Effects.

The most common side effects are cough, dizziness, pyrexia, rash, abdominal pain, musculoskeletal symptoms, and upper respiratory tract infections. Intensity is generally mild to moderate.

Liver injury has been seen in some patients, and may be preceded by signs of an allergic reaction (eg, eosinophilia, pruritic rash, elevated immunoglobulin E). Patients should be informed about signs of an evolving reaction (itchy rash, jaundice, vomiting and/or abdominal pain), and instructed to stop maraviroc and seek medical attention.

During clinical trials, a few patients experienced *cardiovascular events*, including myocardial ischemia and myocardial infarction. Maraviroc should be used with caution in patients with cardiovascular risk factors.

94.8.5 Effects During Pregnancy and Lactation.

There are no adequate and well-controlled studies in pregnant women. Maraviroc is classified in FDA Pregnancy Risk Category B. Women with HIV infections should not breast-feed, owing to the risk of HIV transmission. Whether maraviroc enters breast milk is unknown.

94.8.6 Drug Interactions.

Because maraviroc is metabolized by CYP3A4, drugs that inhibit or induce this enzyme will affect maraviroc levels. Levels will be raised by strong CYP3A4 inhibitors, including protease inhibitors (except tipranavir/ritonavir), delavirdine, ketoconazole, itraconazole, clarithromycin, nefazodone, and telithromycin. Conversely, maraviroc levels will be lowered by strong CYP3A4 inducers, including rifampin, efavirenz, carbamazepine, phenobarbital, phenytoin, and St. John's wort.

94.8.7 Preparations, Dosage, and Administration.

Maraviroc [Selzentry] is supplied in 150- and 300-mg tablets, for dosing with or without food. Dosage depends on other drugs being used as follows:

- Strong CYP3A4 inhibitors—150 mg twice daily
- Strong CYP3A4 inducers—600 mg twice daily
- All other medications—300 mg twice daily

Specific CYP3A4 inhibitors and inducers are indicated above under *Drug Interactions*.

94.9 MANAGEMENT OF HIV INFECTION

Thanks to the drugs available today, HIV infection has been transformed from a near-certain death sentence to a manageable chronic disease. Most patients take several antiretroviral drugs—1110
1111
typically two NRTIs combined with either a PI or NNRTI. These highly effective regimens can reduce plasma HIV to undetectable levels, causing CD4 T-cell counts to return toward normal, thereby restoring some immune function. However, despite these advances, treatment cannot cure HIV. In all cases, discontinuation of antiretroviral drugs has led to a rebound in plasma HIV.

Therapy of HIV disease is often complex. Patients take a combination of drugs for HIV itself—and may take additional drugs to manage treatment side effects (eg, hyperlipidemia, lipodystrophy, depression) along with drugs to prevent or treat opportunistic infections. As a result, the potential

for adverse effects and drug interactions is large. Also, among the drugs used for HIV, emergence of resistance is common. Furthermore, adverse effects and pill burden make adherence difficult. Because of these complexities, management is best done by a clinician with extensive experience in treating HIV.

Much of the discussion that follows is based on treatment guidelines for adult patients developed by the Panel on Clinical Practices for Treatment of HIV infection, convened by the U.S. Department of Health and Human Services (DHHS). This document—*Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*—undergoes periodic updates. The version cited here was released in November 2008. This guideline is available online at aidsinfo.nih.gov, along with companion guidelines for treating pediatric and pregnant patients, and for prophylaxis following HIV exposure.

94.9.1 Screening and Diagnosis

Several tests are used to screen for HIV. They all detect anti-HIV antibodies. If an initial screen produces a positive result, it must be confirmed by a follow-up test.

It should be noted that antibody testing has one important limitation: It can't detect infection immediately following HIV exposure. Why? Because for days to weeks after initial exposure, antibody levels are too low to be measured. Hence, if early diagnosis is needed, a different type of test must be used—specifically, measurement of plasma HIV RNA (see below). If the test for HIV RNA is positive, it should be confirmed with an antibody-based test 2 to 4 months later.

94.9.1.1 Initial Screening.

Prior to 2003, only one type of test was used for HIV screening: an *enzyme-linked immunosorbent assay* (ELISA). ELISAs measure HIV antibodies in blood, and take at least 48 hours to conduct. In reality, however, results are usually not ready for 1 to 2 weeks. Because of this delay, testees must make a return visit. Unfortunately, many don't bother.

Three rapid HIV tests are now available. Two of these—the *OraQuick Rapid HIV-1 Antibody Test* and the *Reveal Rapid HIV-1 Antibody Test*—measure HIV antibodies in *blood*. The third test—the *OraQuick ADVANCE Rapid HIV-1/2 Antibody Test*—measures HIV antibodies in *oral fluid*. With all three tests, results can be ready in minutes, and hence testees needn't return for the results.

94.9.1.2 Follow-up Confirmation.

Positive results from an initial screening test are considered preliminary, and must be confirmed with a second test, usually a Western blot assay. Unlike the initial screening procedures, which test for all types of anti-HIV antibodies, the Western blot measures individual antibody classes. To be considered positive, the Western blot must detect antibodies against at least two of the following three proteins: p24 (a core protein of HIV), and gp41 and gp120/161 (HIV proteins needed for attachment to CD4 T cells).

94.9.2 Laboratory Tests

The principal laboratory tests employed to monitor HIV infection and guide therapy are *CD4 T-cell counts* and *plasma HIV RNA* (viral load) *assays*. Measurement of viral load indicates the magnitude of HIV replication and predicts the rate of CD4 T-cell destruction. In contrast, CD4 T-cell counts indicate how much damage the immune system has already suffered. In addition to these tests, evaluation of *HIV drug resistance* is now done routinely. Some patients will also need tests for *HLA-B*5701* (a genetic variant linked to abacavir hypersensitivity) and for *HIV CCR5 tropism* (a determinant of responsiveness to maraviroc).

94.9.2.1 CD4 T-Cell Counts

The CD4 T-cell count is the principal indicator of how much immunocompetence remains. Accordingly, the CD4 count is a major factor in deciding *when to initiate* antiretroviral therapy, and *when to change drugs* if the regimen is failing. Also, by telling us about immune status, the assay can help guide initiation, discontinuation, and resumption of drugs for opportunistic infections.

As antiretroviral therapy takes effect, CD4 T-cell counts will begin to rise, indicating some return of immune function. With ART, increases of 100 to 250 cells/mm₃ have been observed. Although restoration of CD4 T-cell counts may not produce *complete* immunocompetence, it is often sufficient to permit discontinuation of prophylactic therapy against some opportunistic infections.

Measurement of CD4 T cells should be obtained when HIV infection is diagnosed and every 3 to 6 months thereafter. A healthy range for CD4 T cells is 800 to 1200 cells/mm₃. A 30% reduction is considered significant. Among people with HIV infection, a CD4 T-cell count above 500 cells/mm₃ is considered relatively high. In contrast, a count below 200 cells/mm₃ indicates immunodeficiency.

94.9.2.2 Viral Load (Plasma HIV RNA)

Ongoing treatment of HIV infection is guided primarily by monitoring *viral load*, which is determined by measuring *HIV RNA in plasma*. The source of the RNA is intact HIV virions (virus particles), each of which has two copies of HIV RNA. Guidelines regarding when to measure HIV RNA are summarized in [Table 93-7](#).

Three assays are approved for measuring HIV RNA:

- HIV-1 reverse transcriptase–polymerase chain reaction assay (Amplicor HIV-1 Monitor Test)
- Nucleic acid amplification test for HIV RNA (NucliSens HIV-1 QT)
- Signal amplification nucleic acid probe assay (VERSANT HIV1-RNA)

With all three tests, results are expressed as number of copies of HIV RNA per milliliter. In order to obtain reliable results, blood for HIV RNA determinations must be collected and preserved according to recommended procedures. However, because these tests use different technologies, results will differ depending on the test employed. In order to interpret the results, the clinician must know which test was used.

1111

TABLE 93-7 Times When Plasma HIV RNA Should Be Measured

When to Measure Plasma HIV RNA	Information Obtained	Use of the Information
When a patient presents with a syndrome consistent with acute HIV infection	Establishes presence of HIV when HIV antibody test is negative or indeterminate	Diagnosis of HIV infection
Following initial diagnosis of HIV infection	Establishes baseline viral load	Use in conjunction with CD4 T-cell count for decision to start or defer therapy
Every 3–4 months in HIV patients not on ART	Extent to which viral load has increased	Use in conjunction with CD4 T-cell count for decision to initiate therapy
2–8 weeks after starting or changing ART (preferably within 2–4 weeks)	Initial assessment of drug efficacy	Decision to continue or change therapy
3–4 months after starting ART	Virologic effect of therapy	Decision to continue or change therapy
Every 3–4 months in patients on ART (every 6 months in adherent/stable patients with suppressed HIV RNA for greater than 2–3 years)	Durability of drug effects	Decision to continue or change therapy
When a clinical event or a decline in CD4 T cells occurs	Establishes if the clinical event or decline in CD4 T cells occurred in association with an increase in viral load	Decision to initiate, continue, or change therapy
Adapted from <i>Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents</i> , prepared by the Panel on Clinical Practices for Treatment of HIV Infection, convened by the DHHS, October 6, 2005; updated November 3, 2008.		
ART = antiretroviral therapy.		

Given that the vast majority of HIV in the body is present in lymphoid tissues rather than in the blood, you might ask whether measurement of HIV RNA in *plasma* is a true reflection of the *total body* load of HIV. The answer is “Yes.” Why? Because, when HIV in lymphoid tissues replicates, many of the new virions are released into the blood. As a result, levels of HIV in blood parallel levels in lymphoid tissues. Accordingly, measurement of HIV RNA in blood gives an accurate picture of the total HIV load.

Plasma HIV RNA is the best measurement available for predicting clinical outcome. If HIV RNA is high (eg, 100,000 copies/mL), the prognosis is poor. Conversely, if HIV RNA is low (eg, 500 copies/mL), the risk of disease progression and death is greatly reduced. Accordingly, the goal of therapy is to decrease plasma HIV RNA as much as possible—preferably to a level that is undetectable with current assays (ie, below 50 copies/mL of plasma). It is important to appreciate, however, that even when plasma HIV RNA is undetectable, the patient may still be able to transmit HIV to others—although the risk of transmission is greatly reduced.

When patients are treated with ART, levels of HIV RNA should decline to 10% of baseline within 2 to 8 weeks. After 16 to 20 weeks of treatment, plasma HIV RNA should reach its minimum. With optimal therapy, the minimum reached should be below the limit of detection (less than 50 copies/mL for the Amplicor assay, less than 75 copies/mL for the VERSANT assay, and less than 80 copies/mL for the NucliSens assay).

94.9.2.3 HIV Drug Resistance

Resistance is a significant concern in HIV therapy. In most cases, resistance emerges over the course of treatment as a result of nonadherence to the prescribed regimen. Rarely, resistance results from primary infection with a drug-resistant HIV variant. Resistance tests can be used to guide drug selection, especially when changing a regimen that has failed.

Two major types of resistance assays are employed: *phenotypic assays* and *genotypic assays*. Phenotypic assays measure the ability of HIV to grow in the presence of increasing concentrations of antiretroviral drugs. (The ability to grow in high concentrations indicates resistance.) Genotypic assays are designed to detect resistance-conferring mutations in HIV genes that code for the targets that drugs attack (eg, reverse transcriptase and protease).

Unfortunately, assays for resistance have multiple drawbacks: they are expensive (\$400 to \$1000); turnaround is slow (2 to 4 weeks); sensitivity is low; phenotypic assays can produce false-negative results; and genotypic assays are difficult to interpret. There are no prospective data showing that one type of assay (genotypic or phenotypic) is superior to the other.

When should resistance be tested? According to the 2008 guidelines, the following recommendations apply:

- Test all patients entering HIV care, even if drug therapy will not start immediately. (If drugs are delayed, consider repeating the test.) For these treatment-naïve patients, a genotypic assay is generally preferred.

- Test to aid selection of new drugs when there is virologic failure and HIV RNA levels exceed 1000 copies/mL. (In persons with more than 500 but less than 1000 copies/mL, testing should still be considered.)
- Test when managing suboptimal viral load reduction.
- Test all pregnant women who have not started therapy, and test women who become pregnant while on therapy if they have detectable levels of HIV RNA. In both cases, use a genotypic assay.

1112

94.9.2.4 HLA-B*5701 Screening

1113

As discussed above, the risk of having a hypersensitivity reaction to abacavir is determined largely by a genetic variation, known as HLA-B*5701. Accordingly, patients should be screened for HLA-B*5701 before starting abacavir. If the test is positive, abacavir should not be used, and the patient's positive status should be recorded as an abacavir allergy in his or her medical record. If HLA-B*5701 testing is not available, abacavir may still be used, provided the patient is counseled about possible risk, and monitored for signs of hypersensitivity.

94.9.2.5 CCR5 Tropism

As discussed above, CCR5 is a co-receptor that many strains of HIV must bind with in order to enter CD4 cells. Strains of HIV that use this co-receptor are referred to as being CCR5 tropic. Currently, we have one drug—maraviroc—that can inhibit CCR5 and thereby block HIV entry, but only if the strain is CCR5 tropic. Accordingly, when therapy with maraviroc is under consideration, a CCR5 tropism assay should be performed. At this time, only one commercial assay is available. This assay, known as *Trofile*, takes 2 weeks to perform and requires a plasma HIV RNA level of 1000 copies/mL or more.

94.9.2.6 Therapeutic Drug Monitoring

The term *therapeutic drug monitoring* (TDM) refers to the measurement of plasma drug levels to help guide treatment. For antiretroviral therapy, routine TDM is *not* recommended.

Ideally, by knowing drug levels, we can adjust dosages to maximize antiviral effects and minimize toxicity. However, for TDM to be clinically useful, we must first know a drug's therapeutic range. That is, we need to know the minimal plasma level required for therapeutic effects, and the maximal level we can achieve before toxicity begins. For the antiretroviral drugs, we have some of this information, but not all of it. Specifically, for the PIs, NNRTIs,

and maraviroc (a CCR5 antagonist), we know how low drug levels can fall and still be effective—but we don't know how high levels can rise before toxicity sets in. For the NRTIs, enfuvirtide (a fusion inhibitor), and raltegravir (an integrase inhibitor), we have no information that could help guide treatment. Hence, at this time, monitoring plasma levels of PIs and NNRTIs might be clinically useful, but monitoring levels of other drugs would not.

Why is TDM needed? Because there is considerable variation in drug levels among patients taking the same dose of the same drug. Important sources of variation include differences in drug absorption, and alterations in drug metabolism owing to concurrent use of inducers and/or inhibitors of P450. Specific conditions under which TDM might be useful include

- Concurrent use of an interacting drug
- Pathologic changes in GI, hepatic, or renal function that could alter drug absorption or elimination
- Pregnancy, which can lower drug concentrations
- Treatment of patients who have partially resistant HIV
- Use of a dosing regimen whose efficacy has not been established in clinical trials
- Suspected concentration-dependent drug toxicity
- Lack of expected virologic response in medication-adherent persons.

Are there limitations to TDM? Yes. First, and most important, we lack prospective studies showing that TDM actually improves clinical outcomes. Second, laboratories that can measure plasma levels of antiretroviral drugs are not widely available. Third, as noted already, information on target drug levels—both therapeutic and toxic—is very limited. Because of these factors, routine TDM is generally not recommended.

94.9.3 Treatment of Adult Patients

As discussed above, HIV disease has three phases, an initial acute phase, followed by a prolonged asymptomatic phase, followed by a late symptomatic phase during which AIDS occurs. In the discussion below, we consider drug therapy for each phase separately. However, to facilitate discussion, the phases are discussed in reverse sequence. That is, we discuss symptomatic HIV disease first, then asymptomatic HIV disease, and then acute HIV disease. For patients with symptomatic or acute HIV disease, the benefits of treatment clearly outweigh the risks; hence, immediate and aggressive treatment is recommended. In contrast, for patients with

asymptomatic HIV disease, the benefits of immediate treatment may not outweigh the risks; hence, in some cases, it may be appropriate to delay treatment. During all phases of HIV disease, treatment has five basic goals:

- Maximal and durable suppression of viral load
- Restoration or preservation of immune function
- Improved quality of life
- Reduction of HIV-related morbidity and mortality
- Prevention of vertical HIV transmission (ie, transmission from mother to child, either during pregnancy, delivery, or breast-feeding)

94.9.3.1 Symptomatic HIV Disease

All patients with symptomatic (advanced) HIV disease should receive maximally effective antiretroviral therapy. The virologic goal is to produce maximal and sustained suppression of HIV replication, as evidenced by reduction of plasma HIV RNA to an undetectable level. The treatments employed are referred to as ART, formerly known as HAART (highly active antiretroviral therapy).

ART regimens contain *three or four drugs*. Regimens that contain only two drugs are not generally recommended, and monotherapy should always be avoided, except possibly during pregnancy.

Recommended regimens are summarized in [Table 93-8](#). As indicated, nearly all regimens contain drugs from *two different classes*. Preferred regimens consist of either (1) an NNRTI combined with two NRTIs or (2) a PI (with or without ritonavir boosting) combined with two NRTIs. By using drugs from different classes, we can attack HIV in two different ways (eg, inhibition of reverse transcriptase and protease), and can thereby enhance antiviral effects.

In addition to enhancing antiviral effects, *use of multiple drugs reduces the risk of resistance*. Why? Because the probability that HIV will undergo a mutation that confers simultaneous resistance to three or four drugs is much smaller than the probability of undergoing a mutation that confers resistance to just one drug. For example, if our patient is taking three drugs—efavirenz, zidovudine, and lamivudine—and a virion mutates to a form that is resistant to efavirenz, the other two drugs—zidovudine and lamivudine—will still be effective against the resistant virion, and hence suppression of replication is more likely to be sustained. On the

1113

1114

other hand, if our patient were only taking efavirenz, then treatment would most likely fail. Because of concerns about resistance, when a patient who began treatment with monotherapy is switched to multidrug therapy, we should employ drugs that (1) the patient has not used before and (2) are not cross-resistant with drugs the patient has used before.

TABLE 93-8 Regimens for Initial Therapy of Established HIV Infection

All regimens contain three antiretroviral drugs: NNRTI-based regimens contain an NNRTI combined with 2 NRTIs, and PI-based regimens contain a PI combined with 2 NRTIs.
NNRTI-Based
Preferred
<i>Efavirenz</i> * + tenofovir + emtricitabine
Alternatives
<i>Efavirenz</i> * or <i>nevirapine</i> + abacavir + lamivudine
<i>Efavirenz</i> * or <i>nevirapine</i> + didanosine lamivudine + emtricitabine
<i>Efavirenz</i> * or <i>nevirapine</i> + zidovudine lamivudine
PI-Based
Preferred†
<i>Atazanavir/low-dose ritonavir</i> + 2 NRTIs
<i>Darunavir/low-dose ritonavir</i> + 2 NRTIs
<i>Lopinavir/low-dose ritonavir</i> + 2 NRTIs
<i>Fosamprenavir/low-dose ritonavir</i> + 2 NRTIs
Alternatives†
<i>Saquinavir/low-dose ritonavir</i> + 2 NRTIs
NNRTI = non-nucleoside reverse transcriptase inhibitor; NRTI = nucleoside/nucleotide reverse transcriptase inhibitor, PI = protease inhibitor.

* Efavirenz is not recommended for use in the first trimester of pregnancy or by women with a high pregnancy potential.

† The purpose of low-dose ritonavir in these combinations is to inhibit metabolism of the other PI.

Most regimens employ drugs from only one or two of the six available classes of antiretroviral agents. Because at least four classes of antiretroviral drugs are *not* used, these regimens are considered *class-sparing*. For example, a regimen that employs a PI and NRTIs would spare the use of NNRTIs, fusion inhibitors, integrase inhibitors, and CCR5 inhibitors. A major benefit of class-sparing regimens is that they postpone development of resistance to the unused classes of drugs, and thereby increase the likelihood that the unused classes will be effective for the patient in the future. The principal advantages and disadvantages of class-sparing regimens are summarized in [Table 93-9](#).

Plasma HIV RNA should be monitored to assess the impact of treatment. With ART, plasma HIV RNA should show a 10-fold decrease by 8 weeks, and should be undetectable (ie, less than 50 copies/mL) by 4 to 6 months.

ART cannot cure HIV. Why? Because some HIV virions remain dormant in memory CD4 T cells, and hence escape harm. In all cases, discontinuation of ART has led to a rise in HIV RNA. Accordingly, patients must understand that reducing HIV RNA to undetectable levels does not mean that HIV has been eradicated, and does not mean they have been cured. It only means that the amount of HIV in plasma is too low to measure. Patients with undetectable HIV RNA should be told that they are still infectious, and hence must avoid behaviors that can transmit HIV to others. Because patients still harbor HIV, treatment should continue indefinitely.

A combination of factors—complex regimens, multiple adverse effects, and drug-drug and drug-food interactions—make safe and effective ART difficult. These same factors make patient adherence difficult too. If treatment is to succeed, patients must be fully informed about the importance of strict adherence to the regimen, timing of dosing with regard to meals, and the potential for adverse effects and interactions. Specific measures to promote adherence are discussed below.

94.9.3.2 Chronic Asymptomatic HIV Disease

Making the decision to treat during the chronic asymptomatic phase of HIV disease is more difficult than during the symptomatic phase. Why? Because we lack strong clinical data to guide the decision. For patients in the symptomatic phase, we have solid evidence that the benefits of treatment outweigh the risks, and hence all patients should be given the option of treatment. However, for most patients in the asymptomatic phase, we simply don't know if the benefits will outweigh the risks, and hence the optimal time to initiate therapy is uncertain.

Given this lack of certainty, patients and their prescribers must weigh multiple factors when

deciding whether to initiate ART. Specifically, they must consider the potential benefits and risks of treatment, as well as factors unique to each patient, especially viral load and the existing degree of immunodeficiency. [Table 93-10](#) summarizes these factors.

Early intervention offers several benefits, the most obvious being reduction of viral load. As a result, progression of immunodeficiency is slowed, progression to AIDS is delayed, life may be prolonged, and the risk of transmitting HIV is reduced. In addition, suppression of replication decreases the rate of HIV mutation, and can thereby decrease emergence of drug-resistant mutants. Finally, early treatment decreases the risk of multiple disorders associated with HIV infection, including tuberculosis, Kaposi's sarcoma, and disease of the kidneys, liver, and heart.

1114

1115

TABLE 93-9 Comparison of Class-Sparing Regimens

	PI-Based Regimens (NNRTI and FISparing)	NNRTI-Based Regimens (PI and FISparing)	Dual NRTI-Based Regimens (NNRTI or PI Sparing, and FISparing)
Composition	1 or 2 PIs 2 NRTIs	1 NNRTI 2 NRTIs	3 NRTIs
Potential	Clinical, virologic, and immunologic efficacy well documented.	Easier to use and adhere to than PI-based regimens.	Easier to use and adhere to than PI-based regimens.
Advantages	Resistance requires multiple mutations, and is not a common cause of virologic failure. Targets two steps of HIV replication cycle (protease and reverse transcriptase).	Avoids PI-induced side effects. Causes fewer drug interactions than PIs. Long half-lives.	Avoids PI-related and NNRTI-related side effects. Resistance to 1 NRTI does not confer cross-resistance to all other NRTIs. Drug interactions are more manageable than with PIs.
Potential	Complex, and hence adherence is difficult.	A single mutation can cause resistance to efavirenz, nevirapine, and delaviridine.	Less effective than PI- and NNRTI-based regimens.
Disadvantages	May cause adverse GI effects. Long-term use may cause lipodystrophy, hyperlipidemia, insulin resistance, and osteoporosis. PIs inhibit cytochrome P450, and hence may cause other drugs to accumulate, thereby causing toxicity and increased interactions with other drugs.	Potential for cross-resistance among NNRTIs. Tends to cause skin rash. Potential drug interactions.	Significant risk of virologic failure or early loss of virologic response. Rarely, serious lactic acidosis with hepatic steatosis occurs.

Impact on Future	Preserves NNRTIs and FIs for later use.	Preserves PIs and FIs for later use.	Preserves PIs, NNRTIs, and FIs for later use.
Options	Resistance to 1 PI can produce cross resistance to other PIs.	Resistance to 1 NNRTI usually causes cross-resistance to all other NNRTIs.	Resistance to 1 NRTI causes only limited cross-resistance to other NRTIs.
FI= fusion inhibitor, NNRTI = non-nucleoside reverse transcriptase inhibitor, NRTI = nucleoside/nucleotide reverse transcriptase inhibitor, PI = protease inhibitor.			

Unfortunately, early intervention does have drawbacks. Drug therapy can decrease quality of life. How? By exposing an otherwise symptom-free person to the adverse effects of drugs, including long-term toxicities that may not yet be known. In addition, although it is true that decreasing viral load and replication will decrease spontaneous production of resistant mutants, if resistant mutants *are* produced, the presence of drugs will create selection pressure favoring their emergence. Hence, it is possible that drug therapy will allow resistance to develop sooner than it would have in the absence of drugs. This is especially true if the patient fails to adhere to the regimen. Furthermore, if resistance does develop, drug options for future therapy will be limited, and the risk of transmitting resistance will be increased.

In addition to balancing benefits versus risks, factors unique to the patient must be considered before initiating therapy. Obviously, the patient must be ready to initiate treatment. Also, the patient must be prepared to adhere to a demanding dosing schedule. Finally, the patient's HIV status must be considered. Specifically, we must consider (1) the degree of immunodeficiency, as indicated by CD4 T-cell counts; and (2) the risk of disease progression, as indicated by plasma HIV RNA level.

Some asymptomatic persons, regardless of CD4 count, should always be treated. Specifically, we should always treat pregnant women, people with HIV-associated nephropathy, and people with hepatitis B virus co-infection that requires treatment.

Who should be treated? According to current guidelines, the following persons should definitely receive ART:

- Pregnant women
- Patients with a history of an AIDS-defining illness

- Patients with very low CD4 counts (below 200 cells/mm₃), regardless of HIV/RNA status
- Patients with moderately low CD4 counts (200 to 350 cells/mm₃), regardless of HIV/RNA status
- Patients with HIV-associated nephropathy
- Patients co-infected with hepatitis B virus, when treatment of HBV is indicated

For patients with a high viral load (more than 100,000 copies of HIV RNA/mL) but with reasonable immunologic status (more than 350 CD4 T cells/mL), experts disagree about what to do: Some would start ART immediately, but most would defer treatment. When treatment is deferred, immunologic status (CD4 counts) and virologic status (plasma HIV RNA) should be assessed at least every 3 months. For patients at lowest risk (more than 350 CD4 T cells/mm₃ and less than 100,000 copies of HIV RNA/mL), treatment may be deferred.

If the patient and physician agree to initiate treatment, the goal is the same as with symptomatic patients: reduction of HIV RNA to levels that are undetectable with sensitive assays. As with symptomatic patients, the preferred regimens consist of three or four drugs (see [Table 93-8](#)).

1115

1116

TABLE 93-10 Factors to Consider When Deciding to Initiate Antiretroviral Therapy During the Asymptomatic Phase of HIV Disease (with CD4 T-Cell Counts Above 350 cells/mm³)

Potential Benefits

- Prevention of potentially irreversible injury to the immune system, and maintenance of a higher CD4 count
- Control of viral replication decreases rate of mutation, and can thereby decrease emergence of drug-resistant mutants
- Decreased risk of developing cardiovascular, renal, and liver diseases, and non-AIDS-associated malignancies and infections
- Decreased risk of developing HIV-associated complications that can still occur at higher CD4 counts (>50 cells/mm³), including tuberculosis, non-Hodgkin's lymphoma, Kaposi's sarcoma, peripheral neuropathy, HPV-associated malignancies, and HIV-associated cognitive impairment
- Decreased risk of transmitting HIV to others

Potential Risks

- Development of treatment-associated adverse effects and toxicities
- Exposure of HIV to antiretroviral drugs can lead to earlier emergence of drug-resistant mutants
- If resistance develops, drug options for future therapy will be limited
- If resistance develops, the risk of transmitting resistant mutants will be increased
- Premature use of therapy before the development of more effective, less toxic, and/or better studied drug combinations
- Increased length of treatment, with an increased risk of treatment fatigue
- Long-term toxicity of certain antiretroviral drugs is not yet known

Factors Unique to the Patient

- Willingness to start therapy
- Likelihood of adhering to the regimen
- Degree of immunodeficiency, as indicated by CD4 T-cell count
- Risk of disease progression, as indicated by plasma HIV RNA

94.9.3.3 Acute HIV Disease

All patients with primary acute HIV disease should receive maximally effective antiretroviral therapy. As with symptomatic HIV disease, the preferred regimens consist of three or four drugs (see [Table 93-8](#)).

Early and aggressive intervention offers multiple potential benefits. Of greatest interest is the possibility of eradicating HIV before it gets firmly established, although eradication has not yet been demonstrated. However, even if we can't clear HIV from the body, early treatment still offers the following benefits:

- By suppressing the initial burst of viral replication, treatment may decrease the extent to which HIV disseminates throughout the body.
- By reducing viral load, treatment can preserve immune function, and may also slow the progression of HIV disease.
- By reducing viral load and the rate of replication, treatment can decrease the rate of mutation, and hence can decrease the risk that a drug-resistant virion will emerge.
- By reducing viral load, treatment can decrease the severity of acute illness, and can reduce the risk of viral transmission.

As with asymptomatic HIV disease, treatment of acute HIV infection does have potential drawbacks. Among these are

- Reduction in quality of life because of drug toxicity
- Possible blunting of the early immune response to HIV because of reduced viral presence
- Emergence of drug-resistant HIV if treatment fails

Nonetheless, given the potential benefits of treatment, these drawbacks do not constitute a compelling reason to postpone therapy.

94.9.3.4 Changing the Regimen

There are two basic reasons for changing antiretroviral therapy: treatment failure and drug toxicity. Guidelines for altering the regimen because of these factors are discussed below.

94.9.3.4.1 Treatment Failure.

Treatment failure is arguably the most compelling reason for changing the regimen. Failure is indicated if

- Plasma HIV RNA remains above 400 copies/mL after 24 weeks
- Plasma HIV RNA remains above 50 copies/mL after 48 weeks
- Plasma HIV RNA rebounds after falling to an undetectable level
- CD4 T-cell counts continue to drop despite antiretroviral treatment
- Clinical disease progresses despite antiretroviral treatment

Of these five signs of failure, the first three are the most meaningful, in that they represent a direct measurement of antiretroviral efficacy.

When treatment failure occurs, the reason must be determined. Possibilities include patient nonadherence, poor drug absorption, accelerated drug metabolism (owing to drug interactions), and viral resistance. If nonadherence is the cause, several measures may help (see below). If poor absorption is the cause, changing the timing of administration with respect to meals or increasing the dosage may help. If accelerated metabolism is the cause, increasing the dosage may help. Alternatively, it may be appropriate to substitute a different drug for the one that is causing metabolism to increase. For PIs, accelerated metabolism can be suppressed by adding low-dose ritonavir.

When failure is the result of viral resistance, the preferred response is to change *all* drugs in the regimen. This makes sense in that failure means that HIV is replicating despite current treatment, indicating the presence of at least one HIV strain that is resistant to all drugs in the regimen. If we were to add or change just one drug, resistance would quickly develop to that agent, and failure would recur. The risk of renewed resistance is substantially lower if we change at least two drugs, and even lower if we change three. When we change the regimen, the new drugs should be agents that (1) the patient has not taken previously and (2) are not cross-resistant with drugs the patient has taken previously. Whenever possible, selection of replacement drugs should be guided by resistance testing.

Unfortunately, some patients are already resistant to nearly all available drugs, and hence their options are limited. In such cases, it is rational to continue with the current regimen, which may at least provide partial suppression. To date, there is limited experience with

regimens that consist of either two PIs or a PI plus an NNRTI. Nonetheless, for patients who have no other choice, these combinations are potential options. Because cross-resistance is common between ritonavir and indinavir (two PIs), these drugs should not be substituted for each other. Although there is cross-resistance among NNRTIs, a new NNRTI—etravirine—may be active against HIV strains that are resistant to older NNRTIs.

Three drugs—*enfuvirtide*, *maraviroc*, and *raltegravir*—may be especially valuable for managing treatment failure. As discussed above, all three have unique mechanisms: enfuvirtide is a fusion inhibitor, maraviroc is a CCR5 inhibitor, and raltegravir is an integrase inhibitor. Because these drugs work differently from the older agents—PIs, NRTIs, and NNRTIs—cross-resistance does not exist. Furthermore, since these three drugs are relatively new, patients are unlikely to harbor HIV strains resistant to them.

94.9.3.4.2 Drug Toxicity.

If a patient experiences toxicity typical of a particular drug in the regimen, that drug should be withdrawn and replaced with a drug that is (1) from the same class and (2) of equal efficacy. For example, if a patient taking zidovudine were to develop anemia and neutropenia, zidovudine should be discontinued and replaced with another NRTI (eg, stavudine). Note that, when toxicity is the reason for altering the regimen, changing just one drug is proper, whereas when resistance or suboptimal treatment is the reason, at least two of the drugs should be changed.

94.9.3.5 Promoting Patient Adherence

In order to achieve treatment goals and delay emergence of resistance, strict adherence to the prescribed regimen is critical. Unfortunately, several factors—duration of treatment, possible complexity of the regimen, adverse drug effects, drug-drug interactions, and drug-food interactions—make adhering to antiretroviral therapy unusually hard. The DHHS guidelines identify factors that predict *poor* adherence (eg, poor clinician-patient relationship, active use of alcohol or street drugs, depression and other mental illnesses) as well as factors that predict *good* adherence (eg, availability of emotional and practical support, ability to fit dosing into the daily routine, appreciation that poor adherence will cause treatment failure). Strategies for promoting adherence are summarized below.

94.9.3.5.1 Patient- and Medication-Related Strategies

- Thoroughly educate the patient, using multiple sessions, about the goals of therapy and the importance of adherence.

- Ensure that the patient is motivated to take medication *before* the first prescription is written.
- Negotiate a treatment plan that the patient understands and will commit to.
- Devise a regimen that minimizes pill burden and dosing frequency, and that integrates the dosing schedule with meals and the patient's daily routine.
- Inform the patient about side effects; anticipate side effects and treat them.
- Avoid adverse drug interactions.
- Recruit family and friends to support the treatment plan.
- Organize an adherence support group, or add adherence issues to the agenda of an existing group.

94.9.3.5.2 Clinician- and Healthcare Team–Related Strategies

- Establish trust.
- Serve as educator and information resource.
- Provide ongoing support and monitoring.
- Be available between scheduled visits for questions or problems; provide access via pager when away (including on vacation and at conferences).
- Monitor adherence and, when it's low, intensify management (ie, schedule more frequent visits, recruit family and friends, deploy other team members, provide referral to mental health or chemical dependence services).
- Utilize the healthcare team for all patients, and especially for difficult patients and those with special needs (eg, provide peer educators for adolescents or injection drug users).
- Consider the impact of new diagnoses (eg, depression, liver disease, wasting, recurrent chemical dependency) on adherence, and include adherence intervention in management.

- Utilize all concerned people—pharmacists, peer educators, volunteers, case managers, drug counselors, physician's assistants, and all nurses, including nurse practitioners and research nurses—to reinforce the adherence message.
- Educate the support team about antiretroviral therapy and adherence.

94.9.4 Treatment of Pregnant Patients

94.9.4.1 Basic Principles

In general, *management of HIV infection in pregnant women should follow the same guidelines for managing HIV infection in nonpregnant adults*. Accordingly, ART is recommended for all pregnant women whose clinical, immunologic, or virologic status indicates that treatment is needed—and should be strongly considered for *any* woman, regardless of clinical or immunologic status, if her plasma HIV RNA is above 1000 copies/mL.

When treating HIV infection in pregnant women, the goal is to balance the benefits of treatment—reducing viral load, thereby promoting the health of the mother and decreasing the risk of vertical HIV transmission (ie, transmission to the fetus)—against the risks of treatment—causing teratogenic harm to the fetus. As a rule, the benefits of treatment outweigh the risks. The primary determinants of therapy are the clinical, virologic, and immunologic status of the mother; pregnancy is a secondary consideration. Nonetheless, pregnancy should not be ignored. Because the risk of teratogenesis is greatest during the first 10 to 12 weeks of pregnancy, it might be appropriate to interrupt therapy until the first trimester is over, especially if maternal risk is low (ie, CD4 T-cell count exceeds 350 cells/mm³ and plasma HIV RNA is below 1000 copies/mL). The drawback, of course, is that the viral load will increase, and may thereby intensify HIV disease in the mother and enhance transmission to the fetus. Many experts recommend continuation of maximally effective treatment even during the first trimester. If the mother *does* decide to interrupt treatment, *all* antiretroviral drugs should be stopped. Continuing treatment with just one or two drugs increases the risk of resistance, thereby rendering those drugs ineffective for current or future use by the patient. When treatment resumes, the full regimen should be reinstituted.

1117

1118

TABLE 93-11 Three-Part Zidovudine Regimen for Reducing Perinatal Transmission of HIV*

Time of Administration	Zidovudine Recipient	Dosage
Antepartum	Mother	300 mg PO twice a day <i>or</i> 200 mg PO 3 times a day, initiated between weeks 14 and 34 of gestation and continued until day of delivery
Intrapartum	Mother	2 mg/kg infused IV over 1 hr, then 1 mg/kg/hr by continuous infusion until delivery (cord clamped)
Postpartum	Infant	Start zidovudine within 6–12 hr of birth, and continue for 6 wk. Each dose should be <i>either</i> 2 mg/kg PO <i>or</i> 1.5 mg/kg IV. The dosing interval depends on gestational age as follows: <ul style="list-style-type: none"> • ≥ 35 weeks' gestation—every 6 hr • < 35 weeks' but ≥ 30 weeks' gestation— every 12 hr, advancing to every 8 hr at 2 wk • < 30 weeks' gestation—every 12 hr, advancing to every 8 hr at 4 wk

* Based on DHHS Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission: Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-Infected Women for Maternal Health; and Interventions to Reduce Perinatal HIV Transmission in the United States. Washington, DC: U.S. Department of Health and Human Services, July 8, 2008.

Drug selection is challenging in that information on pharmacokinetics and safety during pregnancy is limited. Two drugs—*delavirdine* and *efavirenz*—pose a risk of fetal harm and should be avoided. All of the *protease inhibitors* increase the risk of gestational diabetes, and hence blood sugar should be monitored closely. *Nevirapine* has been associated with hepatic failure and death among a small number of pregnant patients, and hence should be avoided.

94.9.4.2 Reducing Perinatal HIV Transmission

Most mother-to-child transmission of HIV occurs during the perinatal period, primarily during delivery. Among American children, perinatal transmission accounts for nearly all new HIV infections. In the absence of antiretroviral drugs, the rate of perinatal transmission in the United States is 25%. A high viral load increases risk. The risk for vertical transmission can be reduced by giving antiretroviral drugs to the mother during gestation and labor, and to the

infant for several weeks postpartum. Delivery by cesarean section is recommended for patients with a viral load above 1000 copies/mL.

94.9.4.2.1 Preferred Approach: Initiating Antiretroviral Therapy Early.

The best way to reduce the risk of transmission is to minimize maternal viral load with ART. Treatment should begin early in pregnancy and the regimen should contain *zidovudine*, the preferred drug for preventing perinatal HIV transmission.

Zidovudine treatment involves three parts: (1) oral zidovudine beginning after week 14 of gestation and continuing until delivery, (2) IV zidovudine during labor and delivery, and (3) oral (or IV) zidovudine given to the infant for 6 weeks postpartum. This regimen is founded on results of the Pediatric AIDS Clinical Trials Group Protocol 076. Dosing details are summarized in [Table 93-11](#). To date, zidovudine has not been associated with birth defects, impaired cognition, developmental abnormalities, or malignancies among children exposed to the drug *in utero*. Long-term effects are unknown.

94.9.4.2.2 Alternative Approach: Initiating Antiretroviral Therapy During Labor.

Some HIV-positive women do not receive antiretroviral therapy during pregnancy, either by choice or by being unaware of their HIV status. In these cases, treatment initiated during labor can still reduce the risk of transmission. Several effective regimens are available:

- A single oral dose of *nevirapine* for the mother (at the onset of labor) and for the infant (48 hours postpartum)
- Intravenous *zidovudine* for the mother and oral (or IV) *zidovudine* for the infant (similar to the second and third parts of the three-part zidovudine regimen described above)
- Oral *nevirapine* for both the mother and infant (as above), combined with *zidovudine* for both the mother and infant (as above)
- Oral *zidovudine* plus oral *lamivudine* for the mother (during labor) and for the infant (for the first week postpartum)

Details of these regimens are summarized in [Table 93-12](#).

The *nevirapine-alone* regimen is of special interest. It is simple (just one oral dose for mother and infant) and inexpensive (about \$4), and administration can be directly observed

by a clinician. Simplicity and low cost make the regimen especially attractive for use in countries where healthcare resources are limited.

94.9.4.2.3 Initiating Antiretroviral Therapy Postpartum.

If an HIV-positive mother did not receive antiretroviral therapy during pregnancy or labor, treatment of the infant soon after delivery can confer some protection. Only one regimen is recommended: the 6-week postpartum component of the three-part zidovudine regimen. Treatment should be initiated as soon as possible after delivery, preferably within 6 to 12 hours. In one study, the risk of transmission was reduced from 26.6% in the absence of zidovudine to only 9.3% when zidovudine was initiated within 48 hours of delivery. Some clinicians may choose to combine zidovudine with other antiretroviral drugs, especially if zidovudine resistance is known or suspected. The guidelines recommend testing the infant early for HIV so that, if zidovudine failed to prevent infection, long-term treatment can be started when the infection is still at an early stage.

1118

TABLE 93-12 Intrapartum/Postpartum Regimens for Preventing Perinatal HIV Transmission in the Absence of Antiretroviral Therapy During Pregnancy

Drug	Dosage	Duration of Treatment
Maternal Intrapartum/Postpartum Regimen		
NVP	200 mg PO given once at onset of labor	
ZDV + 3TC	ZDV: Give IV intrapartum as described in Table 93-11 , followed by 300 mg PO twice daily for 1 wk	
	3TC: Starting at labor onset, give 150 mg PO twice daily for 1 wk	
Neonatal Regimen		
NVP	Give 2 mg/kg PO once, between birth and 72 hr of age. If the maternal dose of NVP is given within 2 hr of delivery, dose the infant as soon as possible following birth.	
ZDV + 3TC	ZDV: Start within 6–12 hr of birth, and continue for 6 wk, using the dosage and dosing interval described in Table 93-11	
	3TC: 2 mg/kg PO twice daily, from birth to 1 wk of age	
Adapted from DHHS Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission: Recommendations for Use of Antiretroviral Drugs in Pregnant HIV-Infected Women for Maternal Health; and Interventions to Reduce Perinatal HIV Transmission in the United States. Washington, DC: U.S. Department of Health and Human Services, July 8, 2008.		
NVP = nevirapine, ZDV = zidovudine, 3TC = lamivudine.		

94.9.4.3 Mitochondrial Toxicity from NRTIs

NRTIs can disrupt synthesis of mitochondrial DNA, and can thereby impair mitochondrial function. The major clinical consequence is *lactic acidosis associated with hepatic steatosis*. Mitochondrial injury may also manifest as neuropathy, myopathy, cardiomyopathy, and pancreatitis. Among NRTIs currently in use, the most potent inhibitors of mitochondrial DNA synthesis are didanosine, stavudine, zidovudine, lamivudine, abacavir, and tenofovir.

As discussed above, zidovudine (and other NRTIs) can cause a syndrome characterized by lactic acidosis and hepatic steatosis (fatty degeneration of the liver). Some pregnant women taking didanosine plus stavudine have died. Clinicians and patients should be alert for signs and symptoms of lactic acidosis and hepatic steatosis (nausea, vomiting, abdominal pain, malaise, fatigue, anorexia, and hyperventilation). If these develop, a thorough evaluation

should be conducted. During the third trimester, measurement of electrolytes and hepatic enzymes should be done more frequently.

Some infants with *in utero* exposure to NRTIs have developed symptoms suggestive of mitochondrial damage. Two infants who were exposed to zidovudine plus lamivudine died of severe neurologic disease. However, an association between NRTIs and these deaths has not been firmly established. Available data suggest that, even if *in utero* exposure to NRTIs does pose a risk to the infant, the risk is extremely low and must be compared with the known benefit of using an NRTI (usually zidovudine) during pregnancy.

94.9.4.4 Preconception Counseling and Care

In women with HIV, as in all other women, preconception interventions are directed at optimizing maternal and fetal health. We need to identify risk factors for adverse maternal and fetal outcomes, stabilize existing medical conditions prior to conception, and provide education and counseling targeted at needs of the individual. Specific recommendations for HIV-infected women include the following:

- Selection of effective contraceptive methods to reduce the risk of unintended pregnancy
- Education and counseling about potential effects of both HIV infection and antiretroviral therapy on pregnancy course and outcomes
- Education and counseling regarding perinatal HIV transmission risk and strategies to reduce that risk
- Initiation or modification of antiretroviral therapy prior to conception in order to
 - Avoid fetotoxic agents (eg, efavirenz, delavirdine)
 - Choose agents known to reduce perinatal HIV transmission
 - Attain maximal and stable suppression of maternal viral load
 - Evaluate and manage side effects that can harm the fetus or mother (eg, hyperglycemia, anemia, hepatotoxicity)
- Evaluation for opportunistic infections and initiation of appropriate prophylaxis
- Immunization (eg, for influenza, hepatitis B) as indicated
- Optimization of maternal nutritional status

- Implementation of standard recommendations for preconceptional evaluation and management (eg, assessment of reproductive history and family genetic history; starting folic acid supplementation; screening for infectious disease, including sexually transmitted diseases)
- Screening for maternal psychologic disorders and substance abuse
- Planning for perinatal consultation if desired or indicated

94.9.5 Treatment of Adolescent Patients

The same principles that guide antiretroviral therapy in adults also apply to adolescents. Most studies on HIV replication and antiretroviral therapy have been conducted in adults. However, it is unlikely that HIV behaves any differently in adolescents or that the fundamentals of antiretroviral therapy differ either. In fact, the few studies that have been conducted indicate that the virology of HIV is the same in adolescents and adults, suggesting that optimal antiretroviral regimens should be similar in both populations, as should treatment goals (ie, undetectable viral load, increase in CD4 count). Factors unique to adolescents include adjusting dosage on the basis of puberty stage (early vs. late), and transitioning care from childhood to adulthood. In addition, adherence can be complicated by an unstructured lifestyle and by low self-esteem associated with taking drugs for HIV.

At this time, information on the pharmacokinetics of antiretroviral drugs in adolescents is limited. As a result, dosages for some drugs have not been determined. Hence, when these agents are used, patients should be closely monitored for treatment efficacy and adverse effects.

94.9.6 Treatment of Infants and Young Children

Pediatric HIV infection is common and increasing in developing countries, but rare and declining in the United States. Worldwide in 2007, an estimated 2 million children under the age of 15 were living with HIV/AIDS (90% in sub-Saharan Africa), another 370,000 became newly infected, and 260,000 died due to AIDS. In stark contrast, only 176 new pediatric HIV/AIDS cases were reported in the United States in 2006, down from 954 new AIDS cases in 1992. In almost all cases, pediatric HIV infection is the result of mother-to-child transmission.

In young children, the course of HIV infection is accelerated. Whereas adults generally remain symptom free for a decade or more, many children develop symptoms by their first birthday. Death usually ensues by age 5—even with ART. Why do young children succumb so quickly? Primarily because their immune systems are immature, and hence less able to fend off the virus.

Because immune function is limited, levels of HIV RNA climb higher in toddlers than in adults, and then decline at a much slower rate.

In very young patients, diagnosis and monitoring of HIV infection employs different methods than those used in adolescents and adults. In particular, for infants under 18 months of age, diagnosis should be based on viral load assays, not on antibody tests. For children under 5 years of age, monitoring of immune status should be based on the *percentage* of CD4 cells, not on absolute CD4 counts.

Like older patients, young patients should be treated with a combination of antiretroviral drugs, with the goals of (1) reducing plasma viral HIV to an undetectable level and (2) stabilizing or improving immune status. Two preferred regimens are

- *PI-based ART*: lopinavir/ritonavir *plus* two NRTIs (eg, zidovudine or abacavir plus lamivudine or emtricitabine)
- *NNRTI-based ART*: efavirenz or nevirapine (the choice may depend on the child's age) *plus* two NRTIs (eg, zidovudine plus lamivudine)

Recommended alternatives include

- Two NRTIs *plus* a PI (nelfinavir, atazanavir/ritonavir, or fosamprenavir/ritonavir)
- Three NRTIs (zidovudine plus lamivudine plus abacavir). This combination is recommended only if a PI- or NNRTI-based regimen cannot be used.

Unfortunately, therapy in young patients is confounded by limited information on dosing, pharmacokinetics, and safety, and by the limited availability of pediatric formulations. The information we do have on dosage, formulations, monitoring, and other aspects of therapy can be found in the document titled *Guidelines for the Use of Antiretroviral Agents in Pediatric HIV Infection*, prepared by the Working Group on Anti-retroviral Therapy and Medical Management of HIV-Infected Children, convened by the National Resource Center at the Francois-Xavier Bagnoud Center, the Health Resources and Services Administration, and the National Institutes of Health (NIH). The guidelines, which undergo periodic updates, are available online at <http://www.aidsinfo.nih.gov/guidelines/>.

94.9.7 Postexposure Prophylaxis

One-time exposure to HIV carries a small, but nonetheless real, risk of infection. Sources of exposure include unprotected vaginal or anal intercourse, receptive oral intercourse, sharing a

contaminated needle, accidental needle sticks, and being splashed with blood and other body fluids. Risk is especially high following exposure to a large quantity of infected blood or blood with a high virus titer, and following deep percutaneous penetration with a needle recently removed from the vein of an infected person.

The risk of developing HIV disease after a single exposure can be reduced—but not eliminated—with prophylactic antiretroviral drugs. Presumably, protection results from preventing initial cellular infection and local propagation of HIV, thereby allowing host immune defenses to eliminate the virus before it can become established. To be effective, postexposure prophylaxis (PEP) should be initiated as soon as possible after HIV exposure—preferably within 1 or 2 hours, and no later than 72 hours—and should continue for 28 days. All patients should undergo testing for antibodies against HIV, preferably at the time of exposure, and then 6 weeks, 12 weeks, and 6 months after exposure.

Recommendations for PEP are based on whether the exposure was nonoccupational or occupational, defined as exposure of healthcare personnel while on the job.

94.9.7.1 Nonoccupational Postexposure Prophylaxis

For nonoccupational PEP, current guidelines recommend ART regimens much like those employed for initial therapy of established HIV infection (see [Table 93-8](#)). Two three-drug regimens are preferred:

- *NNRTI-based*: efavirenz + (lamivudine or emtricitabine) + (zidovudine or tenofovir)
- *PI-based*: lopinavir/ritonavir + (lamivudine or emtricitabine) + zidovudine

Detailed information on nonoccupational PEP is available in a document titled *Antiretroviral Postexposure Prophylaxis After Sexual, Injection-Drug Use, or Other Nonoccupational Exposure to HIV in the United States* (revised September 30, 2005), which can be found online at aidsinfo.nih.gov.

94.9.7.2 Occupational Postexposure Prophylaxis

Recommendations for occupational PEP are based on the risk of acquiring HIV, which is determined by multiple factors, including (1) the nature of the exposure (skin penetration vs. body fluid splashed onto nonintact skin or mucous membrane); (2) the severity of the exposure (eg, shallow skin penetration with a solid probe, deep skin penetration with a large-bore hollow needle, surface exposure to small volume of sputum, surface exposure to a large volume of blood); and (3) the HIV status of the exposure source (eg, asymptomatic with a low viral load,

1120

1121

symptomatic with a high viral load). Preferred regimens, based on risk of transmission, may involve one of the following options:

- No PEP
- 2 NRTIs (eg, emtricitabine plus tenofovir)
- PI-based regimen (eg, lopinavir/ritonavir plus emtricitabine plus tenofovir)

Please note that our discussion of this important topic is greatly simplified. For detailed information, you can refer to a document titled *Updated U.S. Public Health Service Guidelines for the Management of Occupational Exposures to HIV and Recommendations for Postexposure Prophylaxis* (revised September 30, 2005), which is available online at aidsinfo.nih.gov. Another valuable resource for recommendations on managing PEP (occupational, nonoccupational, or perinatal) is a 24-hour National HIV/AIDS Clinicians' Consultative Center through the University of California, San Francisco. Information is available online at www.nccc.ucsf.edu/Info/index.html and by calling the PEP hotline at 1-888-448-4911.

94... PROPHYLAXIS AND TREATMENT OF OPPORTUNISTIC INFECTIONS

Individuals with advanced HIV disease are vulnerable to infections caused by opportunistic organisms (ie, organisms that rarely cause serious disease, except when host defenses are compromised). Vulnerability to opportunistic infections (OIs) is caused by immunodeficiency resulting from loss of CD4 T cells. The risk of OIs is greatest in patients with fewer than 200 CD4 T cells/mL. Because of the risk of OIs, patients with low CD4 counts must take antibiotics as prophylaxis. Prior to the advent of ART, prophylaxis was required lifelong.

Since the introduction of ART, the incidence of new OIs has declined dramatically. For example, the incidences of cytomegalovirus retinitis and disseminated mycobacterial infection have fallen by as much as 75% to 80%. In many patients with low CD4 T-cell counts, ART has caused CD4 counts to rise, thereby restoring some immunocompetence and permitting withdrawal of prophylactic drugs. Unfortunately, ART cannot help all patients. In the discussion below, we consider prophylaxis and treatment of OIs in these people. Additional details on the management of OIs can be found in *Guidelines for Prevention and Treatment of Opportunistic Infections in HIV-Infected Adults and Adolescents*, released in April 2009, and *Guidelines for Prevention and Treatment of Opportunistic Infections Among HIV-Exposed and HIV-Infected Children*, released in June 2008. These documents are available online at www.cdc.gov/mmwr/preview/mmwrhtml/rr5804a1.htmf and aidsinfo.nih.gov/contentfiles/Pediatric_OI.pdf, respectively.

94.10.1 ***Pneumocystis* Pneumonia (PCP)**

Pneumocystis pneumonia—known as PCP (for *Pneumocystis pneumonia*)—is a potentially fatal infection caused by *Pneumocystis jiroveci*, formerly misidentified as *Pneumocystis carinii*. Before the use of ART and prophylactic drugs, PCP was the leading cause of death among people with AIDS. At one time, PCP developed in 70% to 80% of HIV-infected people, and killed about 20 to 40%. Following control of an initial bout of PCP, the rate of recurrence was 60% within the first year. In patients receiving ART, PCP is rare, and prophylaxis is often unnecessary.

Clinical manifestations of PCP are generally nonspecific. Early symptoms include fever, cough, dyspnea, chest discomfort, pallor, and cyanosis. In advanced infection, lung morphology is altered. Left untreated, PCP has a mortality rate of 90%.

94.10.1.1 **Treatment of Active PCP.**

The treatment of choice for PCP is *trimethoprim plus sulfamethoxazole* (TMP/SMZ), marketed as Bactrim, Cotrim, and Septra. TMP/SMZ is effective in 90% of patients. Nothing works better. As a rule, clinical improvement is seen in 4 to 8 days. For patients who are severely immunocompromised, *IV pentamidine* [Pentam 300] may be preferred. Alternatives to TMP/SMZ or pentamidine include *atovaquone* [Mepron], *trimethoprim plus dapsone*, *trimetrexate plus leucovorin*, and *primaquine plus clindamycin*. All of these regimens are less effective than TMP/SMZ or pentamidine, but may be better tolerated. Atovaquone is noteworthy for its cost (over \$11,000 wholesale for a year's supply). Dosages are summarized in [Table 93-13](#).

94.10.1.2 **Prophylaxis of PCP.**

Prophylactic therapy is recommended for all patients with a CD4 T-cell count below 200 cells/mL. If ART raises CD4 counts above 200 cells/mL for at least 3 months, prophylaxis can be discontinued.

The preferred medication for prophylaxis is *trimethoprim plus sulfamethoxazole*, given as 1 double-strength tablet each day. For patients who cannot tolerate TMP/SMZ, *aerosolized pentamidine* [NebuPent] may be used instead. Unfortunately, although aerosolized pentamidine is better tolerated than TMP/SMZ, it is less effective. Dosages for TMP/SMZ, pentamidine, and other drugs for prophylaxis are summarized in [Table 93-13](#).

94.10.2 Cytomegalovirus Retinitis

Cytomegalovirus (CMV) retinitis is the leading cause of vision loss in people with AIDS. Prior to availability of ART, the incidence of CMV retinitis was about 40%. Individuals with CD4 T-cell counts below 50 cells/mL are most vulnerable. Left untreated, CMV retinitis invariably leads to retinal necrosis and blindness.

Drug therapy of CMV retinitis proceeds in two stages: induction followed by maintenance. The induction phase reduces CMV load and greatly slows the rate of disease progression. However, induction does not eliminate CMV. Accordingly, maintenance therapy is given to reduce the risk of relapse. Before ART was available, maintenance therapy was required lifelong. However, when ART is able to restore sufficient immune function (by raising CD4 T-cell counts above 100 cells/mL for 3 to 6 months), maintenance therapy can be discontinued.

CMV retinitis can be treated with five agents: ganciclovir, valganciclovir, cidofovir, foscarnet, and fomivirsen (no longer available in the United States). The basic pharmacology of these drugs is discussed in [Chapter 92](#). Three agents—ganciclovir, foscarnet, and cidofovir—may be given intravenously. In addition, ganciclovir may be given orally, by intraocular implant, and by direct injection into the eye. Valganciclovir is administered only by mouth.

1121

TABLE 93-13 Drugs for *Pneumocystis* Pneumonia

Drugs	Dosage	
	Adults and Adolescents	Infants and Young Children
Treatment of Active Infection		
Drugs of Choice		
Trimethoprim sulfamethoxazole	<p>TMP: 15–20 mg/kg/day in 3 or 4 divided doses</p> <p>SMZ: 75–100 mg/kg/day in 3 or 4 divided doses</p> <p>Administer both drugs together, PO or IV, for 14–21 days</p>	Same as adult
Alternatives		
Pentamidine (IV)	4 mg/kg IV daily for 14–21 days	Same as adult
Trimetrexate + leucovorin	<p>TMX: 45 mg/m² IV daily for 21 days</p> <p>LEU: 20 mg/m² PO or IV every 6 hr for 24 days</p>	
Trimethoprim + dapsone	<p>TMP: 5 mg/kg PO 3 times daily for 21 days</p> <p>DAP: 100 mg PO daily for 21 days</p>	
Atovaquone	750 PO mg twice daily for 21 days	
Primaquine + clindamycin	<p>PRM: 15–30 mg base PO daily for 21 days</p> <p>CLN: 600–900 mg IV every 6–8 hr for 21 days or 300–450 mg PO every 6–8 hr for 21 days</p>	
Prophylaxis (Primary or Secondary)		
Drugs of Choice		
Trimethoprim sulfamethoxazole	1 single-strength tablet* PO daily or 1 double-strength tablet* PO daily	<p>TMP: 150 mg/m² PO twice daily</p> <p>SMZ: 750 mg/m² PO twice daily</p> <p>Administer both drugs together on 3 consecutive days each week</p>

Alternatives		
Pentamidine (inhaled)	300 mg inhaled once a month	5 yr and older: Same as adult
Atovaquone	1500 mg PO daily	4–24 months: 45 mg/kg PO daily 1–3 months and >24 months: 30 mg/kg PO daily
Dapsone	50 mg PO twice daily <i>or</i> 100 mg PO daily	2 mg/kg (max of 100 mg) PO daily <i>or</i> 4 mg/kg (max of 200 mg) PO once a week
Dapsone + pyrimethamine + leucovorin	DAP 50 mg PO daily + PYR 50 mg PO every 7 days + LEU 25 mg PO every 7 days	Not recommended

* Single-strength tablet = 80 mg TMP + 400 mg SMZ; double-strength tablet = 160 mg TMP + 800 mg SMZ.

Maintenance therapy is expensive. In 2003, *wholesale* prices for a year's supply were \$13,093 for IV ganciclovir, \$17,794 for PO ganciclovir, \$6500 to \$10,000 for ganciclovir intraocular implants, \$20,904 for IV cidofovir, \$21,582 for PO valganciclovir, and between \$27,770 and \$37,027 for IV foscarnet!

94.10.2.1 Ganciclovir.

Ganciclovir [Cytovene, Vitrasert] is the drug of choice for CMV retinitis. For induction, IV administration is traditional, although intraocular implants or direct intraocular injections may also be used. For maintenance, intraocular implants or daily IV infusions via a central venous catheter are preferred. The implants are more effective than the infusions and cause fewer side effects. To reduce the risk of systemic CMV infection, patients with ocular implants can also take oral ganciclovir. Dose-limiting toxicities of IV ganciclovir are neutropenia and thrombocytopenia secondary to bone marrow suppression. In addition, there is a risk of infection in the central venous catheter.

94.10.2.2 Valganciclovir.

Valganciclovir [Valcyte] is a prodrug version of ganciclovir, but has greater oral bioavailability. Adverse effects are the same as those of ganciclovir. The principal concerns are blood dyscrasias—granulocytopenia, anemia, and thrombocytopenia—secondary to bone marrow suppression.

94.10.2.3 Foscarnet.

Foscarnet [Foscavir] is less well tolerated than ganciclovir and much more expensive. As a rule, the drug is administered by IV infusion—twice daily for induction and once daily for maintenance. To receive infusions daily, patients require an indwelling central venous catheter, and hence face a risk of catheter-related infection. Dose-limiting toxicities are nephrotoxicity, electrolyte imbalance (especially hypocalcemia), genital ulceration, and fluid overload.

94.10.2.4 Cidofovir.

Cidofovir [Vistide] is an IV drug for CMV retinitis. This agent has a longer effective half-life than ganciclovir or foscarnet, and hence can be administered less often. Specifically, whereas ganciclovir and foscarnet must be infused daily for maintenance therapy, cidofovir is infused just once every 2 weeks. Because cidofovir infusions are infrequent, patients do not require an indwelling central catheter, and hence do not face a risk of catheter-related infection. The major dose-limiting toxicities are kidney damage and neutropenia. To reduce the risk of kidney injury, all patients must receive probenecid and IV hydration therapy with each infusion.

94.10.3 ***Mycobacterium tuberculosis* and *Mycobacterium avium* Complex**

Mycobacterium tuberculosis and *Mycobacterium avium* complex (MAC) are slow-growing microbes that require prolonged drug exposure for eradication. Because therapy is prolonged, emergence of resistance is a significant concern. To reduce emergence of resistance, these infections are always treated with multiple drugs—just like HIV itself. Mycobacterial infections and their treatment are discussed at length in [Chapter 89](#). A brief summary of treatment is presented here.

94.10.3.1 **Mycobacterium tuberculosis.**

Tuberculosis is the leading cause of death among patients with AIDS. If the infection is caused by drug-sensitive mycobacteria, treatment is relatively simple. In one protocol, treatment is initiated with a four-drug regimen—*isoniazid*, *rifabutin*, *pyrazinamide*, and *ethambutol*—and then switched to a two-drug regimen—*isoniazid plus rifabutin*—2 months later. Treatment should last for at least 9 months, and for at least 3 months after sputum tests for *M. tuberculosis* become negative. Treatment of drug-resistant infections can be very difficult, sometimes requiring as many as seven drugs. Specific regimens for drug-sensitive and drug-resistant tuberculosis are summarized in [Chapter 89 \(Table 89-1\)](#).

1122

1123

HIV-infected patients with a positive skin test or blood test for tuberculosis should take prophylactic drugs to prevent active *M. tuberculosis* infection. The preferred regimen consists of *isoniazid* for 9 months.

94.10.3.2 **Mycobacterium avium** Complex.

MAC consists of two nearly identical microbes: *Mycobacterium avium* and *Mycobacterium intracellulare*. Infection with MAC begins in the lungs or GI tract, but may later disseminate to the blood, bone marrow, liver, spleen, lymph nodes, brain, kidneys, and skin. Among people with AIDS, disseminated infection is common, being present in 50% at autopsy. Signs and symptoms of disseminated MAC infection include fever, night sweats, weight loss, lethargy, anemia, and abnormal liver function tests.

Primary prophylaxis against MAC is indicated for patients with fewer than 50 CD4 T cells/mL. Either *azithromycin* or *clarithromycin* should be used. If ART produces a 3-month increase in CD4 counts to 100 cells/mL or more, prophylaxis may be discontinued.

If disseminated infection develops, the preferred treatment is *clarithromycin* plus *ethambutol*, with or without *rifabutin*. If needed, azithromycin can be substituted for clarithromycin. In the absence of immune recovery, treatment should continue lifelong. However, if the patient (1) has been treated for at least 12 months and is free of MAC symptoms, and (2) has had a 6-month sustained CD4 elevation (above 100 cells/mL) following ART, discontinuing treatment for MAC is reasonable.

94.10.4 **Toxoplasma** Encephalitis

Toxoplasma gondii is a protozoan of the Sporozoa class. In the immunocompetent host, infection with *T. gondii* is generally benign. However, in the immunocompromised host, infection can be lethal. Among patients with AIDS, toxoplasmosis usually manifests as *encephalitis* (inflammation of the brain or brainstem). Symptoms include fever, headache, seizures, aphasia (loss of speech), lethargy, confusion, dementia, focal neurologic deficits, and progression to coma. *Toxoplasma* encephalitis is most likely late in HIV disease, usually after CD4 T-cell counts fall below 100 cells/mL. In the United States, the incidence of *Toxoplasma* encephalitis among AIDS patients is 3% to 10%, making this the most common opportunistic infection of the CNS in these people.

Patients who are seropositive for *T. gondii* and have low CD4 T-cell counts (below 100 cells/mL) should take drugs to prevent active infection. The preferred regimen is 1 double-strength tablet of

TMP/SMZ daily (the same regimen used to prevent PCP). Prophylaxis can be discontinued if ART produces a sustained (3 month or longer) increase in CD4 T cells (above 200 cells/mL).

If active infection develops, the treatment of choice is *pyrimethamine plus sulfadiazine plus leucovorin*. The sulfadiazine component can cause rash and crystalluria. For patients who cannot tolerate sulfadiazine, *pyrimethamine plus clindamycin plus leucovorin* is an alternative.

Once toxoplasmosis has been controlled, lifelong suppressive therapy is needed. The preferred regimen is *pyrimethamine plus sulfadiazine plus leucovorin*. *Pyrimethamine plus clindamycin* is an alternative. However, clinical experience indicates discontinuing prophylaxis is reasonable in patients who (1) have remained free of encephalitis symptoms and (2) have had a 6-month sustained increase in CD4 T-cell counts (above 200 cells/mL) following ART.

94.10.5 Cryptococcal Meningitis

Cryptococcus neoformans is a fungus that infects 9% to 13% of patients with AIDS. In 80% of these patients, cryptococcosis manifests as meningitis (inflammation of the meninges). The most common symptoms are fever and headache. Other symptoms include nausea, vomiting, photophobia, and altered mental status. Cryptococcal meningitis typically occurs late in HIV disease, usually after CD4 T-cell counts fall below 100 cells/mL. In addition to infecting the meninges, *C. neoformans* can infect the blood, lungs, skin, and prostate.

The treatment of choice for cryptococcal meningitis is *amphotericin B* plus *flucytosine*, infused daily for 2 weeks or longer. The major adverse effect of amphotericin is kidney damage, whereas the major concern with flucytosine is bone marrow suppression (neutropenia, thrombocytopenia). Compared with amphotericin B alone, the combination of amphotericin plus flucytosine decreases rates of treatment failure and relapse. However, mortality rates with both treatments are similar. Because bone-marrow suppression is a significant concern for patients with AIDS, those taking flucytosine should be monitored closely.

After the initial infection has been controlled, patients should continue maintenance therapy indefinitely. The treatment of choice is oral *fluconazole* daily. In the absence of maintenance therapy, patients are at increased risk of relapse and death. However, limited experience suggests that discontinuing maintenance therapy may be reasonable in patients who (1) have no signs or symptoms of cryptococcosis and (2) have developed a 6-month sustained increase in CD4 T-cell counts (200 cells/mL or higher) following ART.

The basic pharmacology of amphotericin B, flucytosine, and fluconazole is discussed in [Chapter 91](#).

94.10.6 Varicella-Zoster Virus Infection

Varicella-zoster virus (VZV) can cause *chickenpox* and *herpes zoster*, also known as *shingles* or simply *zoster*. Among adults with AIDS, VZV infection usually manifests as shingles, which results from reactivation of latent VZV infection. Preferred treatments are oral therapy with *acyclovir* (800 mg 5 times a day for 7 to 10 days), *valacyclovir* (1 gm 3 times a day), or *famciclovir* (500 mg 3 times a day for 5 to 7 days). For patients with disseminated VZV infection, the preferred treatment is IV *acyclovir* (10 mg/kg every 8 hours for 1 to 2 weeks); IV *foscarnet* is an alternative. The basic pharmacology of acyclovir, famciclovir, and foscarnet is discussed in [Chapter 92](#).

94.10.7 Herpes Simplex Virus Infection

Infection with herpes simplex virus (HSV) is common among patients with HIV disease. Lesions may occur at multiple sites, including the lips, tongue, oral cavity, genitals, and perianal region. 1123
1124

In patients with advanced HIV disease, HSV may infect the esophagus, colon, lungs, eyes, and CNS. For infection at all sites, *acyclovir* is the drug of choice. Administration may be oral or IV. Responses usually occur within 3 to 10 days. Duration of treatment ranges from 7 to 21 days. For patients with acyclovir-resistant HSV, IV *foscarnet* or IV *cidofovir* can be used. Patients who experience frequent or severe recurrences can take oral *acyclovir* or *famciclovir* for prophylaxis.

94.10.8 Candidiasis

HIV-infected patients frequently develop infection with *Candida* species, usually *Candida albicans*. The most common sites are the oropharynx and esophagus. Up to 75% of patients experience oral candidiasis (thrush), which often responds to topical therapy, such as “swishing and swallowing” a *nystatin suspension* or sucking *miconazole troches*. Systemic therapy with an oral azole—*fluconazole*, *ketoconazole*, or *itraconazole*—is an alternative. Oral azoles are more convenient than topical therapy and probably more effective. However, they are also more expensive. Prophylaxis of recurrent oral candidiasis is not always needed. However, if recurrence is frequent or severe, chronic intermittent therapy with an oral azole may be considered.

For esophageal candidiasis, systemic therapy is required. Options include oral *ketoconazole*, oral *fluconazole*, and IV *amphotericin B*. All patients with a documented history of esophageal candidiasis should be considered for chronic suppressive therapy with oral *fluconazole*.

^{94...} HIV VACCINES

Development of an HIV vaccine is critical to controlling the AIDS epidemic worldwide. Although HIV infection can now be managed with ART, treatment is expensive, complex, and potentially dangerous, and must continue lifelong. Furthermore, ART is largely unavailable in developing countries, where most AIDS cases occur. Accordingly, vaccine development has been assigned high priority.

^{94.11.1} Obstacles to Vaccine Development

Making a safe and effective vaccine against HIV has proved exceedingly and unexpectedly difficult. Obstacles include the wide global variation in HIV strains, lack of information on natural immunity to HIV, multiple modes of HIV transmission, and lack of an ideal animal model for studying vaccine efficacy. Also, scientists are concerned that the vaccine may need to (1) *prevent* HIV infection, rather than minimize it, and may need to (2) stimulate cell-mediated immunity in addition to humoral immunity. These two concerns are discussed below.

Vaccines do not prevent infection—they only attenuate it. By priming the immune system, vaccines reduce microbial replication and accelerate microbial kill. As a result, infection does not spread as far as it would in an unvaccinated person and does not injure as many cells.

Unfortunately, HIV is different from all other microbes: HIV kills the very cells that are meant to attack it and that vaccination is meant to stimulate. Given the nature of HIV, we must ask, “Will a vaccine that permits HIV to infect even a small number of immune cells be able to contain the infection—or will HIV eventually break through?” The answer is unknown.

Vaccines elicit two kinds of immune responses: *humoral immunity* (production of antibodies) and *cell-mediated immunity* (activation of cytotoxic T lymphocytes, also known as killer T cells). Most authorities agree that, to be effective, an HIV vaccine should elicit both types of responses. Why? The answer is simple: We already know that HIV-positive people produce billions of antibodies against HIV, and yet the infection progresses relentlessly; hence, a vaccine that only stimulates humoral immunity would seem likely to fail. Unfortunately, although it's relatively easy to make a safe vaccine that stimulates humoral immunity, it's much harder to make a safe vaccine that stimulates cellular immunity. Why? Because the best way to stimulate cellular immunity is with a *live virus* vaccine—in this case, a vaccine made from HIV that has been attenuated by removing some of its genes, but has not been killed. The problem is that live virus vaccines pose a risk of infection—a risk that is unacceptable with HIV. The potential danger of

this approach was underscored when monkeys were given a simian version of such a vaccine and subsequently developed simian AIDS, presumably from the vaccine itself.

94.11.2 Current Status of Vaccine Development

Although HIV vaccines have undergone intensive study, the number of promising candidates has dropped substantially. In 2005, 34 candidate HIV vaccines were in early phases of human clinical trials. Today, only a handful are being tested in humans.

To date, only one vaccine—AIDSVAX—has undergone a Phase III trial. AIDSVAX is a bivalent vaccine composed of gp120 proteins, which are found in the outer envelope of HIV. The vaccine activates the antibody-producing arm of the immune system, but does not activate killer T cells. The Phase III trial enrolled 5095 HIV-negative men and 308 HIV-negative women, all considered at high risk of acquiring HIV. One-third of participants received placebo, and two-thirds were injected with vaccine. The result? HIV infection developed in 5.8% of placebo recipients and 5.7% of those given the vaccine. Clearly, AIDSVAX didn't work. These results were especially disappointing in that, in an earlier trial, the vaccine elicited production of neutralizing antibodies in 99% of vaccinees. Apparently, although antibodies were made, they were unable to prevent infection.

The current best hope for protection is to combine a vaccine similar to AIDSVAX (ie, a purified HIV envelope protein) with a “vectored” vaccine, consisting of a harmless virus, such as canarypox, that has been genetically engineered to produce HIV proteins. In Phase I and II clinical trials, this approach appeared safe, and elicited both antibody production and activation of killer T cells.

94... KEEPING CURRENT

Drug therapy of HIV infection is continuously evolving. New drugs are being developed, knowledge of existing drugs is expanding, and new drug combinations are being studied. The following web sites are good sources of very current information:

- **AIDSinfo** (aidsinfo.nih.gov). This site, maintained by the U.S. Department of Health and Human Services, has information on treatment guidelines, drugs, vaccines, and clinical trials. Links to other HIV/AIDS-related sites are there too. Content is presented in English and Spanish. You can sign up for e-mail notification of updates.

1124

1125

- **HIV and AIDS Activities** (www.fda.gov/oashi/aids/hiv.html). This page on the FDA web site offers the latest information on approved drugs, drug development, and drugs in clinical trials.
- **AIDS Education Global Information System** (www.aegis.com). Perhaps the best single web site for information on HIV and AIDS information. The site contains the world's largest HIV/AIDS information base, is continuously updated, and offers chat facilities.

94.12.1

KEY POINTS

- HIV is a retrovirus that, like all other retroviruses, has RNA as its genetic material.
- To infect our cells, HIV must bind to a cell-surface receptor (CD4) as well as a co-receptor (most often CCR5), and then fuse with the cell membrane.
- HIV uses *reverse transcriptase* to convert its RNA into DNA, and *integrase* to insert its DNA into ours.
- HIV uses *protease* to break large HIV polyproteins into their smaller, functional forms.
- The principal targets of HIV are CD4 T cells (helper T lymphocytes). These cells are attacked by HIV because they carry CD4 proteins on their surface, thereby providing HIV with a required point of attachment.
- Because of errors made by reverse transcriptase, HIV can mutate rapidly from a drug-sensitive form into a drug-resistant form.
- HIV infection has three phases. During the initial phase, many patients experience a flu-like acute retroviral syndrome. During the prolonged middle phase, patients are asymptomatic, although CD4 T cells undergo progressive decline. During the late phase, CD4 T cells drop below a critical level (200 cells/mL), rendering the patient vulnerable to opportunistic infections and certain neoplasms.
- HIV replicates rapidly during all phases of HIV infection, including the prolonged phase of clinical latency.
- We have six classes of antiretroviral drugs. Four classes—nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), integrase inhibitors, and protease inhibitors (PIs)—inhibit HIV enzymes. The

two other classes—HIV fusion inhibitors and CCR5 antagonists—work outside CD4 cells to block HIV entry.

- NRTIs suppress HIV replication in two ways: (1) they become incorporated into the growing strand of viral DNA (through the actions of reverse transcriptase), and thereby prevent further strand growth; and (2) they compete with natural nucleoside triphosphates for binding to the active center of reverse transcriptase, and thereby competitively inhibit the enzyme.
- In order to interact with reverse transcriptase, NRTIs must first undergo intracellular conversion to their active (triphosphate) forms.
- All NRTIs can cause lactic acidosis and severe hepatomegaly with steatosis, which can be fatal.
- Zidovudine (an NRTI) can cause severe anemia and neutropenia.
- Didanosine and stavudine (both NRTIs) can cause peripheral neuropathy.
- Didanosine (an NRTI) can cause pancreatitis.
- Abacavir (an NRTI) can cause potentially fatal hypersensitivity reactions, and hence must not be given to patients with the HLA-B*5701 mutation, which predisposes them to abacavir hypersensitivity.
- NNRTIs (eg, efavirenz) differ from NRTIs in that they are not analogs of natural nucleosides, are active as administered, and cause direct noncompetitive inhibition of reverse transcriptase by binding to its active center.
- NNRTIs frequently cause rash, which can be severe and even life threatening.
- Efavirenz is the only NNRTI recommended for first-line therapy of HIV infection.
- Efavirenz frequently causes adverse CNS effects.
- Efavirenz is teratogenic, and must not be used during pregnancy.
- PIs (eg, lopinavir) are among the most effective antiretroviral drugs.
- PIs bind to HIV protease and thereby prevent the enzyme from cleaving HIV polyproteins. As a result, enzymes and structural proteins of HIV remain nonfunctional, and hence the virus remains immature and noninfectious.

- All PIs pose a risk of hyperglycemia, new-onset diabetes, exacerbation of existing diabetes, fat maldistribution, hyperlipidemia, bone loss, elevation of transaminase levels, and increased bleeding in patients with hemophilia.
- All PIs inhibit cytochrome P450, and can thereby decrease metabolism of other drugs, causing their levels to rise. Accordingly, patients should avoid drugs whose accumulation could lead to serious toxicity. Among these are cisapride, alprazolam, triazolam, midazolam, ergot alkaloids, lovastatin, and simvastatin—as well as astemizole and terfenadine, which are no longer available in the United States.
- Ritonavir—a PI that strongly inhibits P450—is often combined with other PIs to raise their plasma levels, and thereby boost antiviral effects.
- Raltegravir, the first HIV integrase inhibitor, prevents insertion of HIV-derived DNA into DNA of CD4 cells, and thereby blocks HIV replication.
- Enfuvirtide, an HIV fusion inhibitor, binds with gp41 on the viral envelope, and thereby blocks entry of HIV into CD4 T cells.
- Enfuvirtide is indicated for HIV infection that is resistant to other antiretroviral drugs.
- The major adverse effect of enfuvirtide is injection-site reactions, which develop in nearly all patients.
- Maraviroc—the first CCR5 antagonist—blocks HIV entry into CD4 cells. Effects are limited to HIV strains that are CCR5 tropic (ie, strains that use the CCR5 co-receptor for cellular entry). Before maraviroc is used, the infecting strains must be tested for CCR5 tropism.

1125

- Treatment of HIV infection has five goals: maximal and durable suppression of viral load, restoration and/or preservation of immune function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of vertical HIV transmission.
- Resistance to antiretroviral drugs is a major problem. To reduce emergence of resistance, these drugs should never be used alone. Rather, they should always be combined with at least one other antiretroviral drug, and preferably two or even three.
- The principal laboratory tests employed to monitor HIV infection and guide therapy are plasma HIV RNA (viral load) and CD4 T-cell counts. Plasma HIV RNA levels indicate

1126

the magnitude of HIV replication and predict the rate of CD4 T-cell destruction, whereas CD4 T-cell counts indicate how much damage the immune system has already suffered.

- Plasma HIV RNA is the best measurement for predicting clinical outcome: if HIV RNA is high, the prognosis is poor; if HIV RNA is low, the risk of disease progression and death is greatly reduced. Accordingly, the goal of antiretroviral therapy is to decrease plasma HIV RNA to levels that are undetectable—now defined as less than 50 copies/mL (using the Amplicor assay).
- Reducing plasma HIV RNA to undetectable levels does not mean that HIV has been eradicated. It only means there is too little HIV to measure. Nonetheless, patients still harbor HIV and are still infectious. Accordingly, treatment should continue indefinitely, and patients should be warned to avoid behaviors that can transmit HIV to others.
- All patients with acute primary HIV disease or advanced (symptomatic) HIV disease should receive maximally effective antiretroviral therapy. Two regimens are preferred: (1) efavirenz (an NNRTI) plus two NRTIs, and (2) ritonavir-boosted lopinavir (a PI) combined with two NRTIs.
- For some patients with chronic asymptomatic HIV disease, it may be appropriate to temporarily postpone antiretroviral therapy.
- In general, the principles that guide antiretroviral therapy in nonpregnant adults also apply during pregnancy. Put another way, women should receive optimal antiretroviral therapy, regardless of their pregnancy status.
- Mother-to-child transmission of HIV occurs primarily during labor and delivery. The risk of transmission can be greatly reduced by ART that minimizes maternal viral load. Zidovudine should be given to the mother during pregnancy (PO) and labor (IV), and to the infant (PO) for 6 weeks postpartum.
- In general, the principles that guide antiretroviral therapy in adults also apply to children.
- An important reason for changing an antiretroviral regimen is treatment failure, indicated by failure of plasma HIV RNA to drop to an undetectable level; a rebound in plasma HIV RNA after falling to an undetectable level; CD4 T-cell counts failing to rise (or continuing to decline); and progression of clinical disease despite antiretroviral treatment.

- When treatment failure is the result of drug resistance, the preferred response is to change *all* drugs in the regimen. Furthermore, the new drugs should be agents that the patient has not taken before and that are not cross-resistant with drugs the patient has taken before.
- Prophylactic drugs can reduce the risk of infection following accidental exposure to HIV (eg, from a needle stick). Prophylaxis is most effective when initiated within 1 or 2 hours, and may be ineffective if initiated after 72 hours.
- Because of declining CD4 T-cell counts, individuals with advanced HIV disease are at risk for opportunistic infections (OIs), and hence may need prophylactic antibiotics.
- By elevating CD4 T-cell counts, ART can restore immune function, and can thereby reduce both the risk of OIs and the need for prophylactic antibiotics.
- Among people with AIDS, *Pneumocystis pneumonia* (PCP) is the most common opportunistic infection.
- The preferred regimen for prophylaxis and treatment of PCP is trimethoprim plus sulfamethoxazole.
- Ganciclovir is the drug of choice for cytomegalovirus retinitis, an OI.

94.12.2 Summary of Major Nursing Implications*

94.1... Implementation: Administration

94.1... Routes

94.1... All NRTIs.

Oral.

94.1... Zidovudine.

Oral and IV.

94.1... Administration

94.1... All NRTIs.

Instruct patients to adhere closely to the prescribed dosing schedule.

94.1... Didanosine.

Instruct patients to take all didanosine formulations 30 minutes before meals or 2 hours after.

Instruct patients taking buffered didanosine tablets to either (1) chew them thoroughly or (2) manually crush them or disperse them in at least 1 ounce of water.

Instruct patients using enteric-coated capsules to swallow them intact.

Instruct patients taking powdered didanosine to pour the contents of one packet into 4 ounces of water (not fruit juice or any other acid-containing beverage), stir the mixture until the drug dissolves (about 2 to 3 minutes), and then drink the solution immediately.

94.1... IV Zidovudine.

Administer IV zidovudine slowly (over 1 hour). Do not mix the solution with biologic or colloidal fluids (eg, blood products, protein solutions). Administer within 8 hours (if stored at room temperature) or within 24 hours (if stored under refrigeration).

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

Plasma HIV RNA.

Success is indicated by a reduction in plasma HIV RNA. With ART, plasma HIV RNA should decline to 10% of baseline within 2 to 8 weeks. After 16 to 20 weeks of treatment, plasma HIV RNA should reach its minimum. Ideally, the minimum will be undetectable with sensitive assays.

CD4 T-Cell Counts.

As viral load decreases, CD4 T-cell counts may rise, indicating some restoration of immune function.

Minimizing Adverse Effects

Anemia and Neutropenia.

Zidovudine can cause severe anemia and neutropenia. Determine hematologic status before treatment and at least every 4 weeks thereafter. In the event of severe anemia (hemoglobin below 7.5 gm/dL or down 25% from the pretreatment baseline) or severe neutropenia (granulocyte count below 750 cells/mL or down 50% from the pretreatment baseline), interrupt treatment until there is evidence of bone marrow recovery. If neutropenia and anemia are less severe, a reduction in dosage may be sufficient. Some patients may require multiple transfusions. Granulocyte colony-stimulating factors can be used to reverse neutropenia. Epoetin alfa (recombinant erythropoietin) can be given to reduce transfusion requirements in patients with anemia, provided endogenous erythropoietin levels are not already elevated.

Lactic Acidosis with Hepatic Steatosis.

Potentially fatal lactic acidosis and hepatic steatosis can occur with all NRTIs. **Inform patients about symptoms—nausea, vomiting, abdominal pain, malaise, fatigue, anorexia, and hyperventilation—and instruct them to report these immediately.** Diagnosis is done by measuring lactate in arterial blood. If lactic acidosis is present, the NRTI should be discontinued.

94.1...

Pancreatitis.

Didanosine can cause potentially fatal pancreatitis. Monitor patients for signs of developing pancreatitis (elevated serum amylase in association with elevated serum triglycerides, decreased serum calcium, and nausea, vomiting, or abdominal pain). If evolving pancreatitis is diagnosed, didanosine should be withdrawn.

94.1...

Peripheral Neuropathy.

Didanosine and *stavudine* can cause painful peripheral neuropathy. **Inform patients about early signs of neuropathy (numbness, tingling, or pain in hands and feet), and instruct them to report these immediately.** Treat pain of severe neuropathy with opioid analgesics. Neuropathy may reverse if these drugs are withdrawn early.

94.1...

Hypersensitivity Reactions.

Abacavir can cause potentially fatal hypersensitivity reactions. Before using abacavir, screen for HLA-B*5701 (a genetic variant associated with abacavir hypersensitivity), and don't use the drug if the variant is detected.

Inform patients of symptoms—fever, rash, myalgia, arthralgia, nausea, vomiting, diarrhea, abdominal pain, pharyngitis, dyspnea, and cough—and instruct them to report these immediately. If a hypersensitivity reaction is diagnosed—or even strongly suspected—abacavir should be discontinued and never used again.

94.1...

HIV Transmission.

Reduction of plasma HIV RNA may create a false sense of safety. Accordingly, **inform patients that, even when HIV RNA is undetectable, they are still infectious, and hence should avoid behaviors that can transmit HIV.**

94.1...

Minimizing Adverse Interactions

94.1...

Zidovudine.

Drugs that are myelosuppressive, nephrotoxic, or directly toxic to circulating blood cells can increase the risk of hematologic toxicity. Drugs of concern include ganciclovir, dapsone, pentamidine, pyrimethamine, trimethoprim/sulfamethoxazole, amphotericin B, flucytosine, vincristine, vinblastine, and doxorubicin.

94.1...	<p>Ribavirin.</p> <p>Ribavirin can increase levels of the active form of <i>didanosine</i>, thereby posing a risk of toxicity. Use the combination with caution.</p>	1127
94.1...	<p>All NRTIs.</p> <p>Giving a combination of NRTIs to a pregnant woman may increase the risk of lactic acidosis and hepatic steatosis. Accordingly, it would seem prudent to avoid these combinations during pregnancy.</p>	1128
94.1...	<p>NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS</p> <p>Delavirdine</p> <p>Efavirenz</p> <p>Etravirine</p> <p>Nevirapine</p>	
94.1...	<p>Preadministration Assessment</p>	
94.1...	<p>Therapeutic Goals</p> <p>Treatment has five goals: maximal and durable suppression of viral load, restoration and/or preservation of immune function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of HIV transmission.</p>	
94.1...	<p>Baseline Data</p> <p>Assess the patient's clinical status and obtain a plasma HIV RNA level, CD4 T-cell count, and liver function tests. Perform a pregnancy test prior to giving efavirenz.</p>	
94.1...	<p>Implementation: Administration</p>	
94.1...	<p>Route</p> <p>Oral.</p>	

94.1...

Administration

94.1...

All NNRTIs.

Instruct patients to adhere closely to the prescribed dosing schedule.

94.1...

Delavirdine.

Inform patients that delavirdine may be taken with or without food. Advise patients who cannot swallow delavirdine tablets whole to mix them with 3 or more ounces of water. Advise patients with achlorhydria to take delavirdine with an acidic beverage, such as orange or cranberry juice.

94.1...

Efavirenz.

Instruct patients to take efavirenz with or without food—but not with a high-fat meal.

94.1...

Nevirapine.

Inform patients that nevirapine may be taken with or without food.

94.1...

Etravirine.

Instruct patients to take etravirine after a meal.

94.1...

Ongoing Evaluation and Interventions

94.1...

Evaluating Therapeutic Effects

See information for NRTIs.

94.1...

Minimizing Adverse Effects

94.1...

Rash.

Rash is common and may range from mild to severe to life threatening. Risk of a severe reaction is greatest with nevirapine. If rash is mild, treat with an antihistamine or topical glucocorticoid. If rash is severe or associated with signs of toxic epidermal necrolysis or Stevens-Johnson syndrome (fever, blistering, oral lesions, conjunctivitis, muscle pain, joint pain), the NNRTI should be withdrawn. To minimize risk, use a low

dosage for the first 14 days of treatment, and then increase the dosage if rash has not occurred.

94.1...

Hepatotoxicity.

NNRTIs can cause hepatotoxicity, which may be severe. Risk is greatest with nevirapine. Perform liver function tests at baseline and periodically thereafter. Interrupt treatment if tests indicate significant liver injury.

94.1...

CNS Symptoms.

Efavirenz frequently causes CNS symptoms (eg, dizziness, insomnia, impaired consciousness, drowsiness, vivid dreams, nightmares). **Inform patients that symptoms typically resolve in 2 to 4 weeks, despite ongoing efavirenz use, and that taking efavirenz at bedtime can minimize CNS effects.** If severe symptoms occur (eg, delusions, hallucinations, severe acute depression), efavirenz should be withdrawn.

94.1...

Birth Defects.

Efavirenz is teratogenic. **Inform women about the potential for fetal harm, and instruct them to use a barrier method of birth control (eg, condom) in conjunction with a hormonal method (eg, oral contraceptive).** Perform a pregnancy test prior to treatment.

94.1...

HIV Transmission.

Reduction of plasma HIV RNA may create a false sense of safety. Accordingly, **inform patients that, even when HIV RNA is undetectable, they are still infectious, and hence must avoid behaviors that can transmit HIV.**

94.1...

Minimizing Adverse Interactions

94.1...

Nevirapine.

Nevirapine *induces* cytochrome P450 and can thereby decrease levels of other drugs. Effects on *protease inhibitors*, *oral contraceptives*, and *methadone* are of particular concern.

94.1...

Combining nevirapine with *St. John's wort* or *rifampin*, which also induce P450, can decrease nevirapine levels, and hence these combinations should be avoided.

Delavirdine.

Delavirdine *inhibits* P450, and can thereby increase levels of other drugs. To avoid toxicity from excessive drug levels, patients must not take *cisapride*, *alprazolam*, *midazolam*, *triazolam*, *lovastatin*, or *simvastatin*—or *astemizole* or *terfenadine*, which are no longer available in the United States. In addition, the following drugs should be used with caution: *indinavir*, *saquinavir*, *clarithromycin*, *dapsone*, *warfarin*, *quinidine*, *ergot alkaloids*, *PDE5 inhibitors* (eg, *sildenafil* [Viagra]), and the *dihydropyridine-type calcium channel blockers*.

Antacids, *histamine₂-receptor blockers*, *proton pump inhibitors*, and *buffered formulations* of *didanosine* can decrease absorption of *delavirdine*.

94.1...

Efavirenz.

Efavirenz *competes with other drugs for metabolism by P450*, and can thereby increase their levels. To avoid toxicity from excessive drug levels, the patient must not take *astemizole*, *terfenadine*, *cisapride*, *midazolam*, *triazolam*, *dihydroergotamine*, or *ergotamine*.

Efavirenz *induces P450*, and can thereby accelerate metabolism of other drugs, including two PIs: *saquinavir* and *indinavir*. Avoid combined use with *saquinavir*. Increase *indinavir* dosage.

St. John's wort induces P450, and can thereby reduce levels of *efavirenz*. The combination should not be used.

1128

94.1...

Etravirine.

Etravirine competes with other drugs for metabolism by P450 and can thereby increase their levels.

The plasma concentration of *etravirine* is lowered by use of *St. John's wort*, *anticonvulsants*, *darunavir/ritonavir*, *systemic dexamethasone*, *rifampin*, *rifapentine*, *ritonavir*, *saquinavir/ritonavir*, and *tipranavir/ritonavir*.

1129

94.1...

PROTEASE INHIBITORS

Amprenavir

Atazanavir

Darunavir

Fosamprenavir

Indinavir

Lopinavir/Ritonavir

Nelfinavir

Ritonavir

Saquinavir

Tipranavir

94.1...

Preadministration Assessment

94.1...

Therapeutic Goals

Treatment has five goals: maximal and durable suppression of viral load, restoration and/or preservation of immune function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of vertical HIV transmission.

94.1...

Baseline Data

Assess the patient's clinical status and obtain a plasma HIV RNA level and CD4 T-cell count. Measure serum transaminases and blood glucose.

94.1...

Identifying High-Risk Patients

Amprenavir oral solution is contraindicated for pregnant women, children less than 4 years old, patients with renal or hepatic failure, and patients taking disulfiram or metronidazole.

94.1...

Implementation: Administration

94.1...

Route

All protease inhibitors are taken orally.

94.1...

Administration and Storage

94.1...

All Protease Inhibitors.

Instruct patients to adhere closely to the prescribed dosing schedule.

94.1...

Atazanavir, Darunavir, Tipranavir, Lopinavir/Ritonavir.

Instruct patients to take these products with food.

94.1...

Amprenavir.

Inform patients they can take amprenavir without food or with food—as long as the food is low fat.

94.1...

Indinavir.

Instruct patients to administer indinavir (1) with water but on an empty stomach (ie, 1 hour before a meal or 2 hours after); or (2) with skim milk, coffee, tea, or a low-fat meal (eg, corn flakes with skim milk and sugar), but not with a large meal. Instruct patients to store indinavir at room temperature in the package supplied by the manufacturer.

94.1...

Nelfinavir.

Instruct patients to take nelfinavir with food. Instruct patients to mix the powder formulation with a small amount of water, milk, formula, soy formula, soy milk,

or dietary supplement, but not with acidic foods or juices (eg, applesauce, apple juice, orange juice).

94.1...

Ritonavir.

Advise patients to take ritonavir with food. Instruct patients to mix the oral solution with chocolate milk, Ensure, or Advera (within 1 hour of administration) to improve the taste. Instruct patients to store ritonavir refrigerated (2°C to 8°C; 36°F to 46°F) and protected from light.

94.1...

Saquinavir.

Instruct patients to take saquinavir tablets or capsules with a ritonavir boost; dosing may be done with or without food.

94.1...

Ongoing Evaluation and Interventions

94.1...

Evaluating Therapeutic Effects

See information for NRTIs.

94.1...

Minimizing Adverse Effects

94.1...

Hyperglycemia/Diabetes.

All PIs can cause hyperglycemia and diabetes. **Instruct patients to report any symptoms (eg, polydipsia, polyphagia, polyuria).** In patients with existing diabetes, monitor blood glucose closely. To detect new-onset diabetes, measure blood glucose at baseline, every 3 to 4 months during the first year of treatment, and less frequently thereafter. Diabetes can be treated with insulin and oral antidiabetic agents (eg, metformin).

94.1...

Fat Maldistribution.

Forewarn patients that all PIs may cause accumulation of fat on the waist, stomach, breasts, and back of the neck, and loss of fat from the face, arms, buttocks, and legs. Drug withdrawal may cause symptoms to resolve, but is not recommended. Injections of Sculptra can be used to compensate for loss of facial fat.

94.1...

Hyperlipidemia.

All PIs can elevate cholesterol and triglycerides, thereby posing a risk of cardiovascular events and pancreatitis. Monitoring plasma cholesterol and triglycerides every 3 to 4 months may be wise. If drugs are given to lower lipid levels, two agents—lovastatin and simvastatin—should be avoided.

94.1...

Increased Bleeding in Patients with Hemophilia.

Protease inhibitors may increase the risk of bleeding in patients with hemophilia. Higher doses of coagulation factors may be needed.

94.1...

Increased Transaminase Levels.

Protease inhibitors can increase serum levels of transaminases. Exercise caution in patients with chronic liver disease (eg, hepatitis B or C, cirrhosis). Measure serum transaminases before treatment and periodically thereafter.

94.1...

Nephrolithiasis.

Indinavir can cause nephrolithiasis. Management consists of hydration and interruption of indinavir for 1 to 3 days. **To decrease the risk of nephrolithiasis, instruct patients to consume at least 48 ounces (1.5 L) of water daily.**

94.1...

Bone Loss.

Protease inhibitors may promote bone loss. **To reduce risk, encourage patients to ensure adequate intake of calcium and vitamin D.** Osteoporosis can be treated with bisphosphonates, raloxifene, calcitonin, or teriparatide.

94.1...

Diarrhea.

Nelfinavir causes diarrhea in 20% to 32% of patients. Diarrhea can usually be managed with loperamide or some other over-the-counter antidiarrheal drug.

1129

94.1...

Propylene Glycol Toxicity.

Amprenavir oral solution contains a large amount of *propylene glycol*, which can accumulate to toxic levels in certain patients. Accordingly, this formulation must not be given to pregnant women, children less than 4 years old, patients with renal or

1130

hepatic failure, and patients taking disulfiram or metronidazole. **Advise patients to avoid alcohol.**

Atrioventricular Block.

Atazanavir prolongs the PR interval, and can thereby promote AV block. Use with caution in patients with cardiac conduction disturbances.

Indirect Hyperbilirubinemia.

Atazanavir and *indinavir* can raise plasma levels of unconjugated bilirubin (indirect bilirubin). Be alert for jaundice (yellowing of the skin) and icterus (yellowing of the eyes), which reverse upon drug withdrawal.

HIV Transmission.

Reduction of plasma HIV RNA may create a false sense of safety. Accordingly, **inform patients that, even when HIV RNA is undetectable, they may still be infectious, and hence should avoid behaviors that can transmit HIV.**

Minimizing Adverse Interactions

Interactions Resulting from Inhibition of P450.

All PIs inhibit cytochrome P450, and can thereby increase levels of other drugs. To avoid serious toxicity from excessive drug levels, patients must not take *cisapride*, *alprazolam*, *triazolam*, *midazolam*, *ergot alkaloids*, *lovastatin*, or *simvastatin*—or *astemizole* or *terfenadine*, which are no longer available in the United States.

Ritonavir Boosting.

Because ritonavir is a powerful inhibitor of P450, the drug is often combined with other PIs to raise their blood levels, and thereby boost antiviral effects.

Didanosine.

Buffered formulations of didanosine decrease absorption of *indinavir* and *ritonavir*. Accordingly, buffered didanosine should be administered 1 or 2 hours apart from these drugs.

94.1...

Rifampin.

Rifampin induces P450, and can thereby reduce levels of the PIs. Concurrent use with all PIs should be avoided.

94.1...

Oral Contraceptives.

Ritonavir, *nelfinavir*, and *amprenavir* can reduce levels of ethinyl estradiol, a component of many oral contraceptives. **Advise patients to use an alternative form of birth control.**

94.1...

Vitamin E.

Amprenavir formulations contain a large amount of vitamin E. **Warn patients not to take vitamin E supplements.**

94.1...

St. John's Wort.

St. John's wort induces P450, and can thereby reduce levels of PIs. **Warn patients not to use St. John's wort.**

94.1...

ENFUVIRTIDE, AN HIV FUSION INHIBITOR

94.1...

Preadministration Assessment

94.1...

Therapeutic Goals

Enfuvirtide is indicated for HIV infection that is resistant to traditional antiretroviral drugs.

Treatment has five goals: maximal and durable suppression of viral load, restoration and/or preservation of immune function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of vertical HIV transmission.

94.1...

Baseline Data

Assess the patient's clinical status and obtain a plasma HIV RNA level and CD4 T-cell count.

94.1...

Identifying High-Risk Patients

Use enfuvirtide with *caution* in patients who have pneumonia risk factors: low initial CD4 cell counts, high initial viral load, IV drug use, smoking, and a history of lung disease.

94.1...

Implementation: Administration

94.1...

Route

Subcutaneous.

94.1...

Preparation and Storage

Teach patients to reconstitute powdered enfuvirtide with 1.1 mL of sterile water for injection, and advise them to either (1) inject the solution immediately or (2) store it cold (2°C to 8°C; 36°F to 46°F) for up to 24 hours. Inform patients that powdered enfuvirtide may be stored at room temperature.

94.1...

Administration

Educate patients on aseptic injection technique, and instruct them to

- **Make injections into the upper arm, thigh, or abdomen (but not the navel)**
- **Rotate the injection site**
- **Avoid sites where there is an ongoing injection-site reaction or tissue that is scarred or bruised**

Instruct patients that, before using stored enfuvirtide solution, they should bring it to room temperature and make sure it is clear, colorless, and free of bubbles and particulate matter.

Ongoing Evaluation and Interventions

94.1...

Evaluating Therapeutic Effects

See information for NRTIs.

94.1...	<h2>Minimizing Adverse Effects</h2> <h3>Injection-Site Reactions.</h3> <p>Inform patients about manifestations of ISRs—pain, tenderness, erythema, induration, nodules, cysts, pruritus, and ecchymosis—and forewarn them that these occur in nearly everyone. Inform patients that they can reduce the risk of a severe ISR by rotating the injection site, avoiding sites with an active ISR, and avoiding unnecessarily deep injections. Instruct patients to seek immediate medical attention if a severe ISR occurs or if local infection develops.</p>	
94.1...	<h3>Pneumonia.</h3> <p>Enfuvirtide may increase the risk of bacterial pneumonia. Inform patients about signs of pneumonia—cough, fever, and breathing difficulties—and instruct them to report these immediately. Use enfuvirtide with caution in patients who have pneumonia risk factors.</p>	1130
94.1...	<h3>Hypersensitivity Reactions.</h3> <p>Enfuvirtide may cause hypersensitivity reactions, manifesting as rash, fever, nausea, vomiting, chills, rigors, hypotension, or elevated serum transaminases, or possibly as respiratory distress, glomerulonephritis, Guillain-Barré syndrome, or primary immune complex reaction. Inform patients about signs of hypersensitivity, and advise them to report them immediately. If a systemic hypersensitivity reaction occurs, enfuvirtide should be discontinued and never used again.</p>	1131
94.1...	<h3>HIV Transmission.</h3> <p>Reduction of plasma HIV RNA may create a false sense of safety. Accordingly, inform patients that, even when HIV RNA is undetectable, they are still infectious, and hence must avoid behaviors that can transmit HIV.</p>	

MARAVIROC, A CCR5 ANTAGONIST

Preadministration Assessment

Therapeutic Goals

Maraviroc, in combination with other antiretroviral, is indicated for treatment-experienced adults infected with CCR5-tropic strains of HIV that are resistant to multiple other drugs.

Treatment has five goals: maximal and durable suppression of viral load, restoration and/or preservation of immune function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of vertical HIV transmission.

Baseline Data

Assess the patient's clinical status and obtain the following laboratory data: HIV RNA level, CD4 T-cell count, serum transaminases, and proof that the infecting HIV strain is CCR5 tropic.

Identifying High-Risk Patients

Patients with elevated liver function and cardiovascular disease must be monitored carefully.

Implementation: Administration

Route

Oral.

Administration

Inform patients that dosing may be done with or without food.

Advise patients that, if they forget to take a dose, to take the missed dose as soon as possible, and take the next scheduled dose at its regular time. If the time to the next dose is less than 6 hours, the patient should skip the missed dose and take the next dose as scheduled.

Ongoing Evaluation and Interventions

Evaluating Therapeutic Effects

See information for NRTIs.

Minimizing Adverse Effects

Hepatotoxicity.

Liver injury has been seen in some patients, and may be preceded by evidence of an allergic reaction. **Inform patients about signs of an evolving reaction (itchy rash, yellow skin, dark urine, vomiting and/or abdominal pain), and instruct them stop maraviroc and seek medical attention.**

Cardiovascular Events.

During clinical trials, a few patients experienced cardiovascular events, including myocardial ischemia and myocardial infarction. Exercise caution in patients with cardiovascular risk factors.

HIV Transmission.

Inform patients that maraviroc is not a cure for HIV infection; it does not reduce the risk of transmission of HIV to others through sexual contact, sharing needles, or blood contamination.

RALTEGRAVIR, AN INTEGRASE INHIBITOR

Preadministration Assessment

Therapeutic Goals

Raltegravir is used for treatment-experienced adults infected with HIV-1 strains resistant to multiple antiretroviral agents.

Treatment has five goals: maximal and durable suppression of viral load, restoration and/or preservation of immune function, improvement of quality of life, reduction of HIV-related morbidity and mortality, and prevention of vertical HIV transmission.

94.1...

Baseline Data

Assess the patient's clinical status and obtain a plasma HIV RNA level and CD4 T-cell count.

⁹⁵CHAPTER 94 Drug Therapy of Sexually Transmitted Diseases

Sexually transmitted diseases (STDs), also known as sexually transmitted infections, are infectious diseases transmitted primarily through sexual contact. STDs are very common in the United States and constitute a major public health problem. In 2003, the Centers for Disease Control and Prevention (CDC) received more than 1.2 million *reports* of STDs, including 877,478 cases of genital *Chlamydia trachomatis* infection and 335,104 cases of gonorrhea. However, because most STDs go unreported, the actual incidence is much higher, estimated at 19 million new infections a year, 50% of which occur in people under the age of 25. According to the CDC, Americans now have a 25% lifetime risk of contracting an STD.

Our objective in this chapter is to describe the principal STDs and provide an overview of their treatment. [Table 94-1](#) presents a summary of the common STDs, causative organisms, and drugs of choice for treatment. The basic pharmacology of these drugs is discussed in other chapters.

In 2006, the CDC revised its “Sexually Transmitted Diseases Treatment Guidelines,” updating the 2002 version. Most of the treatment recommendations presented in this chapter reflect the 2006 guidelines, which are available online at www.cdc.gov/std/treatment. This site also contains any adjustments to the guidelines (eg, the 2007 changes regarding gonococcal infection), and hence should be consulted for the most current recommendations.

^{95.1}CHLAMYDIA TRACHOMATIS INFECTIONS

^{95.1.1} Characteristics

Chlamydia trachomatis is the most common cause of bacterial STD in the United States ([Fig. 94-1](#)), infecting about 2.8 million people annually. The various strains of *Chlamydia* can cause genital tract infections, proctitis, conjunctivitis, and lymphogranuloma venereum (LGV), as well as ophthalmia and pneumonia in infants. Infection is frequently asymptomatic in women, and may also be asymptomatic in men. In women, untreated infection can cause pelvic inflammatory disease (PID), ectopic pregnancy, and infertility. The CDC estimates that chlamydial infections cause sterility in up to 50,000 women each year, primarily from fallopian tube scarring. Because infection is often asymptomatic in women, and because sequelae can be serious, the CDC now recommends annual screening for all sexually active women under age 25. Screening is also recommended for women over age 25 who have a new sex partner or multiple partners.

95.1.2 Treatment

95.1.2.1 Adults and Adolescents.

For uncomplicated urethral, cervical, or rectal infections in adults or adolescents, two treatments are recommended: (1) a single 1-gm oral dose of *azithromycin* [Zithromax] or (2) 100 mg of *doxycycline* [Vibramycin, others] PO twice daily for 7 days.

95.1.2.2 Infection in Pregnancy.

Preferred treatments for *C. trachomatis* infection during pregnancy are (1) a single 1-gm oral dose of *azithromycin* or (2) 500 mg of *amoxicillin* PO 3 times daily for 7 days. Although doxycycline and other tetracyclines are active against *C. trachomatis*, these drugs are contraindicated because they can damage fetal teeth and bones. Similarly, sulfisoxazole and other sulfonamides are active, but are contraindicated near term because they can promote kernicterus in the infant.

95.1.2.3 Infants.

About half the infants born to women with cervical *C. trachomatis* acquire the infection during delivery, putting them at risk for *pneumonia* and *conjunctivitis* (ophthalmia neonatorum). Pneumonia is generally not severe and lasts about 6 weeks. Conjunctivitis does not result in blindness and spontaneously resolves in 6 months. The preferred treatment for both infections is oral *erythromycin base* or *erythromycin succinate*, 12.5 mg/kg 4 times daily for 14 days. Although topical erythromycin, tetracycline, or silver nitrate may be given to prevent conjunctivitis, these

1132

1134

Figure 94-1 Incidence of sexually transmitted diseases.

drugs are not completely effective—and they have no effect on pneumonia.

1134

TABLE 94-1 Drug Therapy of Sexually Transmitted Diseases*

Disease or Syndrome	Recommended Treatment	Causative Organism(s)
Chlamydial Infections		<i>Chlamydia trachomatis</i>
Adults and adolescents	Azithromycin, 1 gm PO once <i>or</i> Doxycycline, 100 mg PO 2 times/day × 7 days	
Children		
<45 kg	Erythromycin base/ethylsuccinate, 12.5 mg/kg PO 4 times/day × 14 days	
≥45 kg but <8 yr old	Azithromycin, 1 gm PO once	
≥8 yr old	Azithromycin, 1 gm PO once <i>or</i> Doxycycline, 100 mg PO 2 times/day × 7 days	
Pregnant women	Azithromycin, 1 gm PO once <i>or</i> Amoxicillin, 500 mg PO 3 times/day × 7 days	
Newborns: ophthalmia or pneumonia	Erythromycin base/ethylsuccinate, 12.5 mg/kg PO 4 times/day × 14 days	
Lymphogranuloma venereum	Doxycycline, 100 mg PO 2 times/day × 21 days	
Gonococcal Infections (Gonorrhea)		<i>Neisseria gonorrhoeae</i>
Urethritis, [†] cervicitis, [†] proctitis [†]	Cefixime, 400 mg PO once <i>or</i> Ceftriaxone, 125 mg IM once	

Pharyngitis†	Ceftriaxone, 125 mg IM once	
Disseminated gonococcal infection (DGI) in adults	Ceftriaxone, 1 gm IM or IV every 24 hr, continuing for 24–48 hr after improvement begins	
DGI with meningitis	Ceftriaxone, 1–2 gm IV every 12 hr × 10–14 days	
DGI with endocarditis	Ceftriaxone, 1–2 gm IV every 12 hr × 28 days or more	
Conjunctivitis	Ceftriaxone, 1 gm IM once	
Newborns		
Ophthalmia	Ceftriaxone, 25–50 mg/kg IM or IV once (max 125 mg)	
Disseminated infection or scalp abscess	Ceftriaxone, 25–50 mg/kg IM or IV once/day × 7 days <i>or</i> Cefotaxime, 25 mg/kg IM or IV every 12 hr × 7 days	
Children		
Arthritis, bacteremia	Ceftriaxone, 50 mg/kg IM or IV (max 1 gm) × 7 days	
Vulvovaginitis, cervicitis, proctitis, pharyngitis, urethritis	If 45 kg or less, ceftriaxone 125 mg IM once; if more than 45 kg, same as adult	
Nongonococcal Urethritis		<i>Chlamydia trachomatis, Ureaplasma urealyticum, Trichomonas vaginalis, Mycoplasma genitalium</i>
Acute infection	Azithromycin, 1 gm PO once <i>or</i> Doxycycline, 100 mg PO 2 times/day × 7 days	
Recurrent/persistent	Metronidazole (2 gm PO once) or tinidazole (2 gm PO once), <i>either one plus</i> azithromycin (1 gm PO once) if the drug was not used for initial therapy	
Treatment resistant, <i>Mycoplasma genitalium</i> suspected‡	Azithromycin, 500 mg on day 1, followed by 250 mg/day for 4 days	

Pelvic Inflammatory Disease		<i>Neisseria gonorrhoeae, Chlamydia trachomatis, others</i>
Inpatients	Cefoxitin (2 gm IV every 6 hr) or cefotetan (2 gm IV every 12 hr), <i>either one plus</i> doxycycline (100 mg IV or PO every 12 hr) for 14 days	
Outpatients	Cefoxitin (2 gm IM once, boosted with probenecid 1 g PO once) or ceftriaxone (250 mg IM once), <i>either one plus</i> doxycycline (100 mg PO 2 times/day × 14 days), <i>with or without</i> metronidazole (500 mg PO 2 times/day × 14 days)	
Sexually Acquired Epididymitis	Ceftriaxone (250 mg IM once) <i>plus</i> doxycycline (100 mg PO 2 times/day × 10 days) Ofloxacin (300 mg PO twice daily × 10 days) <i>or</i> Levofloxacin (500 mg PO twice daily × 10 days)	<i>Chlamydia trachomatis, Neisseria gonorrhoeae, Escherichia coli</i>
Syphilis		<i>Treponema pallidum</i>
Primary syphilis, secondary syphilis, and early latent syphilis	<i>Adults:</i> Benzathine penicillin G, 2.4 million units IM once <i>Children:</i> Benzathine penicillin G, 50,000 units/kg IM once (up to a max of 2.4 million units)	
Late latent syphilis or latent syphilis of unknown duration	<i>Adults:</i> Benzathine penicillin G, 2.4 million units IM once/wk for 3 wk <i>Children:</i> Benzathine penicillin G, 50,000 units/kg IM once/wk for 3 wk (up to a max of 7.2 million units)	
Tertiary syphilis	Benzathine penicillin G, 2.4 million units IM once/wk for 3 wk (must rule out CNS involvement)	
Neurosyphilis	Aqueous crystalline penicillin G, 18–24 million units IV daily for 10–14 days, administered by continuous infusion or in separate doses of 3–4 million units each every 4 hr	
Congenital syphilis	Aqueous crystalline penicillin G, 50,000 units/kg IV every 12 hr for the first 7 days of life, followed by 50,000 units/kg every 8 hr for the next 3 days <i>or</i> Procaine penicillin G, 50,000 units/kg IM once daily for 10 days <i>or</i> Benzathine penicillin G, 50,000 units/kg IM once	

Pharmacology for Nursing Care, 7th Edition

Acquired Immunodeficiency Syndrome (AIDS)	See Chapter 93	Human immunodeficiency virus
Bacterial Vaginosis	Metronidazole, 500 mg PO 2 times/day × 7 days <i>or</i>	<i>Gardnerella vaginalis</i> ,
Nonpregnant women	Metronidazole gel (0.75%), 1 full applicator (5 gm) intravaginally once/day × 5 days <i>or</i>	<i>Mycoplasma hominis</i> , various anaerobes
	Clindamycin cream (2%), 1 full applicator (5 gm) intravaginally at bedtime × 7 days	
Pregnant women	Metronidazole, 500 mg PO 2 times/day × 7 days <i>or</i>	
	Metronidazole, 250 mg PO 3 times/day × 7 days <i>or</i>	
	Clindamycin 300 mg PO 2 times/day × 7 days	
Trichomoniasis	Metronidazole, 2 gm PO once <i>or</i>	<i>Trichomonas vaginalis</i>
	Tinidazole, 2 gm PO once	
Chancroid	Azithromycin, 1 gm PO once <i>or</i>	<i>Haemophilus ducreyi</i>
	Ceftriaxone, 250 mg IM once <i>or</i>	
	Ciprofloxacin, 500 mg PO 2 times/day × 3 days <i>or</i>	
	Erythromycin base, 500 mg PO 3 times/day × 7 days	

Genital Herpes Simplex Virus Infections		Herpes simplex virus
First episode, genital herpes	<p>Acyclovir, 400 mg PO 3 times/day × 7–10 days (or longer) <i>or</i></p> <p>Acyclovir, 200 mg PO 5 times/day × 7–10 days (or longer) <i>or</i></p> <p>Famciclovir, 250 mg PO 3 times/day × 7–10 days (or longer) <i>or</i></p> <p>Valacyclovir, 1 gm PO 2 times/day × 7–10 days (or longer)</p>	
First episode, proctitis, stomatitis, or pharyngitis	Acyclovir, 400 mg PO 5 times/day for 7–10 days (or longer)	
Severe infection	Acyclovir 5–10 mg/kg IV every 8 hr for 2–7 days or until clinical improvement, then PO acyclovir to complete at least 10 days	
Recurrent episodes	<p>Acyclovir, 800 mg PO 2 times/day × 5 days <i>or</i></p> <p>Acyclovir, 800 mg PO 3 times/day × 2 days <i>or</i></p> <p>Acyclovir, 400 mg PO 3 times/day × 5 days <i>or</i></p> <p>Acyclovir, 200 mg PO 5 times/day × 5 days <i>or</i></p> <p>Famciclovir, 125 mg PO 2 times/day × 5 days <i>or</i></p> <p>Famciclovir, 1 gm 2 times/day × 1 day <i>or</i></p> <p>Valacyclovir, 500 mg PO 2 times/day × 3 days <i>or</i></p> <p>Valacyclovir, 1 gm PO once/day × 5 days</p>	
Daily suppressive therapy	<p>Acyclovir, 400 mg PO 2 times/day <i>or</i></p> <p>Famciclovir, 250 mg PO 2 times/day <i>or</i></p> <p>Valacyclovir, 500 mg PO once/day <i>or</i></p> <p>Valacyclovir, 1 gm PO once/day</p>	
Neonatal herpes	Acyclovir, 20 mg/kg IV every 8 hr × 14 days (for skin, eye, or mucous membrane infection) or × 21 days (for disseminated or CNS infection)	

Proctitis	Ceftriaxone (125 mg IM once) <i>plus</i> doxycycline (100 mg PO 2 times/day × 7 days)	<i>Chlamydia trachomatis, Neisseria gonorrhoeae, Treponema pallidum, herpes simplex virus</i>
Venereal Warts [†]		Human papillomavirus
External genital	<i>Patient administered:</i> Podofilox 0.5% solution or gel (topical) <i>or</i> Imiquimod 5% cream (topical) <i>or</i> Kunecatechins 15% ointment <i>Provider administered:</i> Cryotherapy with liquid nitrogen or cryoprobe <i>or</i> Podophyllin 10–25% (topical) <i>or</i> TCA or BCA 80–90% (topical) <i>or</i> Surgical excision	
Anal	Cryotherapy with liquid nitrogen <i>or</i> TCA or BCA (80–90%) applied to warts <i>or</i> Surgical excision	
Vaginal	Cryotherapy with liquid nitrogen <i>or</i> TCA or BCA (80–90%) applied to warts	
Urethral meatus	Cryotherapy with liquid nitrogen <i>or</i> Podophyllin 10–25% (topical)	

* Recommendations from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines—2006. MMWR Morb Mortal Wkly Rep 55 (RR-11):1–94, 2006. Recommendations here include CDC's 2007 update on gonococcal infections.

† If chlamydia infection has not been ruled out, add either azithromycin (1 gm PO once) or doxycycline (100 mg PO twice daily for 7 days).

‡ This recommendation is based on clinical studies. It is not in the 2006 CDC Treatment Guidelines.

§ Intravenous therapy with cefotetan, cefoxitin, and doxycycline may be discontinued 24 hours after the patient improves clinically; oral therapy with doxycycline should continue to complete 14 days of therapy.

¶ BCA = bichloroacetic acid, TCA = trichloroacetic acid.

95.1.2.4 Preadolescent Children.

Although infection in preadolescent children can result from perinatal transmission, sexual abuse is the more likely cause, especially in children more than 2 years old. Because of the legal implications, diagnosis must be definitive. Treatment depends on the age and weight of the child. For children who weigh less than 45 kg, the preferred treatment is oral *erythromycin base* or *erythromycin ethylsuccinate*, 12.5 mg/kg 4 times a day for 14 days. For children who weigh 45 kg or more, but are less than 8 years old, the preferred treatment is a single 1-gm oral dose of *azithromycin*. For children at least 8 years old, the preferred treatments are (1) a single 1-gm oral dose of *azithromycin* or (2) 100 mg of *doxycycline* PO twice daily for 7 days.

95.1.2.5 Lymphogranuloma Venereum.

LGV is caused by a unique strain of *C. trachomatis*. Transmission is strictly by sexual contact. 1135

LGV is most common in tropical countries, but does occur in the United States, especially in the South. Infection begins as a small erosion or papule in the genital region. From this site, the organism migrates to regional lymph nodes, causing swelling, tenderness, and blockage of lymphatic flow. Tremendous enlargement of the genitalia may result. The enlarged nodes, called buboes, may break open and drain. The treatment of choice for genital, inguinal, and anorectal LGV is 100 mg of *doxycycline* PO twice daily for 21 days. 1136

95.2 GONOCOCCAL INFECTIONS

95.2.1 Characteristics

Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus often referred to as the gonococcus. The incidence of gonorrhea is high: In the United States, about 600,000 new infections occur each year, making gonorrhea second only to chlamydia as our most common STD. Gonorrhea is transmitted almost exclusively by sexual contact.

The intensity of symptoms differs between men and women. In men, the main symptoms are a burning sensation during urination and a pus-like discharge from the penis. In contrast, gonorrhea in women is often asymptomatic, or may present as mild cervicitis. However, serious infection of

female reproductive structures (vagina, urethra, cervix, ovaries, fallopian tubes) can occur, ultimately resulting in sterility. Among people who engage in oral sex, the mouth and throat can become infected, causing sore throat and tonsillitis. Among people who engage in receptive anal sex, the rectum can become infected, causing a purulent discharge and constant urge to move the bowels. Bacteremia can develop in males and females, causing cutaneous lesions, arthritis, and, rarely, meningitis and endocarditis.

95.2.2 Treatment

Because of antibiotic resistance, treatment of gonorrhea has changed over the years—and undoubtedly will continue to evolve. In the 1930s, virtually all strains of the gonococcus were sensitive to sulfonamides. However, within a decade, sulfonamide resistance had become common. Fortunately, by that time penicillin had become available, and the drug was active against all gonococcal strains. However, in 1976, organisms resistant to penicillin began to emerge. More recently, resistance to fluoroquinolones has begun common. As a result, in 2007 *the CDC recommended against using fluoroquinolones for gonorrhea*, leaving cephalosporins as the preferred treatments.

A high percentage of patients with gonococcal infection are co-infected with *C. trachomatis*. Accordingly, when they are treated for gonorrhea, they should be treated for *C. trachomatis* as well (unless the infection has been ruled out). As noted above, the preferred drugs for *C. trachomatis* are *doxycycline* and *azithromycin*.

95.2.2.1 Urethral, Cervical, and Rectal Infection.

Because fluoroquinolones are no longer recommended for gonorrhea, preferred options are limited to two drugs: *cefixime* [Suprax], 400 mg PO once, and *ceftriaxone* [Rocephin], 125 mg IM once.

95.2.2.2 Pharyngeal Infection.

Gonococcal infection of the pharynx is more difficult to treat than infection of the urethra, cervix, or rectum, and hence parenteral therapy is recommended. The preferred treatment is *ceftriaxone* (125 mg once) given by IM injection.

95.2.2.3 Conjunctivitis.

Gonococcal conjunctivitis can be reliably eradicated with *ceftriaxone*, 1 gm IM once. Treatment also includes washing the infected eye with saline solution once.

95.2.2.4 Disseminated Gonococcal Infection.

Disseminated gonococcal infection (DGI) occurs secondary to gonococcal bacteremia. Symptoms include petechial or pustular skin lesions, arthritis, arthralgia, and tenosynovitis (inflammation of the tendon sheath). Endocarditis and meningitis occur rarely. Strains of *N. gonorrhoeae* that cause DGI are uncommon in the United States. In the absence of endocarditis or meningitis, treatment consists of IM or IV *ceftriaxone*, 1 gm every 24 hours. For patients with endocarditis or meningitis, the preferred treatment is IV *ceftriaxone*, 1 to 2 gm every 12 hours.

95.2.2.5 Neonatal Infection.

Neonatal gonococcal infection is acquired through contact with infected cervical exudates during delivery. Infection can be limited to the eyes or it may be disseminated.

Gonococcal *neonatal ophthalmia* is a serious infection. The initial symptom is conjunctivitis. Over time, other structures of the eye become involved. Blindness can result. The recommended therapy is IV or IM *ceftriaxone*, 25 to 50 mg/kg once.

To protect against neonatal ophthalmia, a topical antibiotic should be instilled into both eyes immediately postpartum—as required by law in most states. Any of three agents may be used: 0.5% *erythromycin*, 1% *silver nitrate*, or 1% *tetracycline*. It should be noted, however, that topical antibiotics are not 100% effective. Furthermore, if parenteral therapy is to be used, topical therapy is unnecessary.

In neonates, *disseminated gonococcal infection* is rare. Possible manifestations include sepsis, arthritis, meningitis, and scalp abscesses. There are two recommended treatments: (1) *ceftriaxone*, 25 to 50 mg/kg IV or IM once a day for 7 days (or 10 to 14 days if meningitis is present); and (2) *cefotaxime*, 25 mg/kg IV or IM every 12 hours for 7 days (or 10 to 14 days if meningitis is present).

95.2.2.6 Preadolescent Children.

Among preadolescent children, the cause of gonococcal infection is sexual abuse. Vaginal, anorectal, and pharyngeal infections are most common. Because of legal implications, diagnosis must be definitive. Growing a specimen in culture is the preferred technique.

Treatment depends on the type of infection and the weight of the child. For children who have localized infection (vulvovaginitis, cervicitis, urethritis, pharyngitis, proctitis) and who weigh

45 kg or less, the preferred treatment is a single 125-mg IM dose of *ceftriaxone*. For children with localized infection who weigh more than 45 kg, treatment is the same as for adults. For children of any weight who have systemic infection (bacteremia, arthritis), the preferred treatment is *ceftriaxone*, 50 mg/kg IM or IV once daily for 7 days.

95.3 NONGONOCOCCAL URETHRITIS

Nongonococcal urethritis (NGU) is defined as urethritis caused by any organism other than *N. gonorrhoeae*, the gonococcus. The most common infectious agent is *C. trachomatis* (15% to 55%). 1136
Other likely agents are *Ureaplasma urealyticum*, *Trichomonas vaginalis*, and *Mycoplasma genitalium*. 1137
NGU is diagnosed by the presence of polymorphonuclear leukocytes and a negative culture for *N. gonorrhoeae*. The infection is especially prevalent among sexually active adolescent girls. The recommended treatment is either (1) *azithromycin* [Zithromax], 1 gm PO once, or (2) *doxycycline* [Vibramycin], 100 mg PO twice daily for 7 days. For persistent or recurrent NGU, two drugs are recommended: *metronidazole* [Flagyl] (2 gm PO once) or *tinidazole* [Tindamax] (2 gm PO once)—in combination with *azithromycin* (1 gm PO once) if *azithromycin* had not been used during initial therapy. If the infection still fails to respond, the cause may be *Mycoplasma genitalium*. Unfortunately, we have no easy tests for this bacterium, and hence definitive diagnosis may not be possible. Nonetheless, when *M. genitalium* is suspected, a trial with *azithromycin* may be warranted. One effective regimen consists of 500 mg on day 1, followed by 250 mg on days 2 through 5.

95.4 PELVIC INFLAMMATORY DISEASE

Acute PID is a syndrome that includes endometritis, pelvic peritonitis, tubo-ovarian abscess, and inflammation of the fallopian tubes. Infertility can result. Prominent symptoms are abdominal pain, vaginal discharge, and fever. Most frequently, PID is caused by *N. gonorrhoeae*, *C. trachomatis*, or both. However, *Mycoplasma hominis* as well as assorted anaerobic and facultative bacteria may also be present.

Because multiple organisms are likely to be involved, drug therapy must provide broad coverage. Since no single drug can do this, combination therapy is required. For the *hospitalized patient*, treatment can be initiated with either *cefoxitin* (2 gm IV every 6 hours) or *cefotetan* (2 gm IV every 12 hours), combined with *doxycycline* (100 mg IV or PO every 12 hours). After symptoms resolve, IV therapy can be discontinued—but must be followed by oral *doxycycline* (100 mg every 12 hours) to complete a 14-day course of treatment.

Outpatients can be treated with either *ceftriaxone* (250 mg IM once) or *cefoxitin* (2 gm IM once, boosted with probenecid, 1 gm PO once). Treatment should also include *doxycycline* (100 mg PO twice daily for 14 days), with or without *metronidazole* (500 mg PO twice daily for 14 days). Because PID can be difficult to treat, and since the consequences of failure can be severe (eg, sterility), many experts recommend that *all* patients receive IV antibiotics in a hospital.

95.5 ACUTE EPIDIDYMITIS

Epididymitis may be acquired by sexual contact or nonsexually. Sexually acquired epididymitis is usually caused by *N. gonorrhoeae*, *C. trachomatis*, or both. It may also be caused by *Escherichia coli*. The syndrome occurs primarily in young adults (under 35 years old) and may be associated with urethritis. Primary symptoms are fever accompanied by pain in the back of the testicles that develops over the course of several hours. For patients with gonococcal or chlamydial infection, the recommended treatment is *ceftriaxone* [Rocephin], 250 mg IM once, plus *doxycycline* [Vibramycin, others], 100 mg PO twice daily for 7 days. For patients with infection caused by *E. coli*, the recommended treatment is *ofloxacin* [Floxin], 300 mg PO twice daily for 10 days, or *levofloxacin* [Levaquin], 500 mg PO once daily for 10 days. Testicular pain can be managed with analgesics, bed rest, and ice packs.

Non–sexually transmitted epididymitis generally occurs in older men and in men who have had urinary tract instrumentation. Causative organisms are gram-negative enteric bacilli and *Pseudomonas*. Ofloxacin can be used for treatment.

95.6 SYPHILIS

Syphilis is caused by the spirochete *Treponema pallidum*. In the United States, the incidence of syphilis increased during the 1980s, decreased throughout the 1990s, but then has risen steadily through the 2000s. In 2006, reported cases of primary and secondary syphilis totaled 9756. Fortunately, *T. pallidum* has remained highly responsive to penicillin, the treatment of choice.

95.6.1 Characteristics.

Syphilis develops in three stages, termed *primary*, *secondary*, and *tertiary*. *Treponema pallidum* enters the body by penetrating the mucous membranes of the mouth, vagina, or urethra of the penis. After an incubation period of 1 to 4 weeks, a primary lesion, called a chancre, develops at the site of entry. The chancre is a hard, red, protruding, painless sore. Nearby lymph nodes may become swollen. Within a few weeks the chancre heals spontaneously, although *T. pallidum* is still present. In clinical practice, chancres are rarely seen, especially in females.

Two to 6 weeks after the chancre heals, secondary syphilis develops. Symptoms result from spread of *T. pallidum* via the bloodstream. Skin lesions and flu-like symptoms (fever, headache, reduced appetite, general malaise) are typical. Enlarged lymph nodes and joint pain may also be present. The symptoms of secondary syphilis resolve in 4 to 8 weeks—but may recur episodically over the next 3 to 4 years.

Tertiary syphilis develops 5 to 40 years after the initial infection. Almost any organ can be involved. Infection of the brain—neurosyphilis—is common, and can cause senility, paralysis, and severe psychiatric symptoms. The heart valves and aorta can be damaged. Lesions can also occur in the skin, bones, joints, and eyes. The risk of neurosyphilis is increased in individuals with HIV infection.

Infants exposed to *T. pallidum in utero* can be born with syphilis. Early signs of congenital syphilis include sores, rhinitis, and severe tenderness over bones.

95.6.2 Treatment.

Penicillin G is the drug of choice for all stages of syphilis. The form and dosage of penicillin G depend on the disease stage. *Early syphilis* (primary, secondary, or latent syphilis of less than 1 year's duration) is treated with a single IM dose of benzathine penicillin G (2.4 million units for adults and 50,000 units/kg for children). *Late syphilis* (more than 1 year's duration) is also treated with IM benzathine penicillin G. However, instead of receiving a single dose, adults and children receive three doses 1 week apart. *Neurosyphilis* requires more aggressive therapy. The recommended treatment is 18 to 24 million units of penicillin G daily for 10 to 14 days, administered either by continuous infusion or in separate doses (3 to 4 million units every 4 hours). For *congenital syphilis*, three regimens have been recommended: (1) IV penicillin G, 50,000 units/kg every 12 hours for the first 7 postnatal days followed by the same dose every 8 hours for 3 more days; (2) IM procaine penicillin G, 50,000 units/kg once daily for 10 days, or (3) benzathine penicillin G, 50,000 units IM once. *Syphilis in pregnancy* should be treated with penicillin G, using a dosage appropriate to the stage of the disease.

How should patients with *penicillin allergy* be treated? For *nonpregnant* patients, either *doxycycline* or *tetracycline* may be used. Dosages for *early syphilis* are (1) doxycycline, 100 mg PO twice daily for 14 days, or (2) tetracycline, 500 mg PO 4 times a day for 14 days. Dosages for *late syphilis* are the same as for early syphilis, except that treatment lasts 4 weeks instead of 2. If the patient is *pregnant*, the U.S. Public Health Service recommends that she go through a penicillin-allergy desensitization protocol to permit penicillin use, rather than substituting another drug for penicillin.

A study reported in 2005 indicates that a single 2-gm oral dose of *azithromycin* [Zithromax] may be as effective as IM benzathine penicillin G for prevention and treatment of syphilis. However, there is concern that routine use of the drug might lead to increased resistance.

95.7 ACQUIRED IMMUNODEFICIENCY SYNDROME

AIDS is caused by the human immunodeficiency virus (HIV). The pathophysiology and treatment of HIV infection are discussed in [Chapter 93](#).

95.8 BACTERIAL VAGINOSIS

Bacterial vaginosis results from an alteration in vaginal microflora. Organisms responsible for the syndrome include *Gardnerella vaginalis* (also known as *Haemophilus vaginalis*), *Mycoplasma hominis*, and various anaerobes. The syndrome occurs most commonly in sexually active women, although it may not actually be transmitted sexually. Bacterial vaginosis is characterized by a malodorous vaginal discharge, elevation of vaginal pH (above 4.5), and generation of a fishy odor when vaginal secretions are mixed with 10% potassium hydroxide.

Drug route depends on pregnancy status. For women who are *not* pregnant, treatment may be oral or topical. For women who *are* pregnant, only oral drugs are used.

95.8.1 Nonpregnant Women.

The recommended oral therapy is *metronidazole* [Flagyl], 500 mg twice a day for 7 days. Two intravaginal options are recommended: (1) *metronidazole* (0.75% gel), 5 gm once daily for 5 days; and (2) standard *clindamycin* (2% cream), sold as Cleocin and ClindaMax, 5 gm every evening for 7 days. In addition, a new 2% *clindamycin cream* [Clindesse] may be used. Clindesse cream is formulated to adhere to the vaginal mucosa for several days, and hence can clear bacterial vaginosis with just one application.

95.8.2 Pregnant Women.

Treatment is oral only. Two drugs are recommended: *clindamycin* and *metronidazole*. For clindamycin, the dosage is 300 mg twice daily for 7 days. For metronidazole, dosage may be either (1) 500 mg twice daily for 1 week or (2) 250 mg 3 times a day for 1 week.

95.9 TRICHOMONIASIS

Trichomoniasis is an STD caused by *Trichomonas vaginalis*. In men, the infection is usually asymptomatic. In women, the infection may be asymptomatic or may cause a diffuse, malodorous, yellow-green vaginal discharge, along with burning and itching sensations. Most infections can be eliminated with a single, 2-gm oral dose of either *metronidazole* [Flagyl, others] or *tinidazole* [Tindamax]. Dosing can be repeated in the event of treatment failure. Male partners of infected women should always be treated, even if asymptomatic. Although some clinicians remain concerned about giving metronidazole during pregnancy, there is no evidence that the drug causes birth defects in humans.

95... CHANCROID

Chancroid, also known as soft chancre, is caused by *Haemophilus ducreyi*. Transmission is primarily by sexual contact. The infection is characterized by a painful, ragged ulcer at the site of inoculation, usually the external genitalia. Regional lymph nodes may be swollen. Multiple secondary lesions may develop. Although primarily a tropical disease, chancroid has become an important STD in the United States. There are four recommended treatments: (1) *azithromycin* [Zithromax], 1 gm PO once; (2) *ceftriaxone* [Rocephin], 250 mg IM once; (3) *ciprofloxacin* [Cipro], 500 mg PO twice a day for 3 days; and (4) *erythromycin base*, 500 mg PO 3 times a day for 7 days.

95... HERPES SIMPLEX VIRUS INFECTIONS

95.11.1 Characteristics.

Most genital herpes infections are caused by herpes simplex virus type 2 (HSV-2). A few genital infections are caused by herpes simplex virus type 1, the herpesvirus that causes cold sores. Genital herpes is transmitted primarily by sexual contact. In the United States, the infection has reached epidemic proportions. Over 45 million people are affected, and 1.6 million new cases develop each year. There is no cure.

Symptoms of primary infection develop 6 to 8 days after contact. In females, blisters or vesicles can appear on the perianal skin, labia, vagina, cervix, and foreskin of the clitoris. In males, vesicles develop on the penis and occasionally on the testicles. Painful urination and a watery discharge can occur in both sexes. Also, the patient may experience systemic symptoms: fever, headache, myalgia, and tender, swollen lymph nodes in the affected region. Within days, the original blisters can evolve into large, painful, ulcer-like sores. Over the next 2 to 3 weeks, all

symptoms resolve spontaneously. However, this does not indicate cure: The virus remains present in a latent state and can cause recurrence. Because current therapy can't eliminate the virus, symptoms may recur for life. However, for some patients, subsequent episodes become progressively shorter and less severe, and in rare cases may cease entirely. Transmission of HSV-2 can occur when symptoms are absent as well as when symptoms are present. Using a condom reduces the risk of transmission.

95.11.2 Neonatal Infection.

Genital herpes in pregnant women can be transmitted to the infant. Transmission can occur *in utero*, which is very rare, or during delivery. Infection acquired *in utero* can result in spontaneous abortion or fetal malformation. Infection acquired during delivery can cause severe neurologic damage and even death. To protect the infant during delivery, birth should be accomplished by cesarean section if the mother has an active infection.

95.11.3 Treatment.

Genital herpes can be treated with three drugs: *acyclovir* [Zovirax], *famciclovir* [Famvir], and *valacyclovir* [Valtrex]. These agents cannot eliminate the virus, but they can reduce symptoms and shorten the duration of pain and viral shedding. Patients with recurrent infections may take these drugs every day or just when symptoms appear. Continuous daily administration reduces the frequency and intensity of episodes, whereas episodic treatment simply reduces symptoms once an episode has begun. Dosing information is summarized in [Table 94-1](#).

95.11.4 Suppression of Transmission.

Valacyclovir (500 mg once daily) can decrease transmission of genital herpes by 50%. No other drug has been shown to reduce transmission of this STD—or any other STD, for that matter. Unfortunately, treatment is somewhat expensive, costing about \$3.50 a day (about \$1280 a year). Also, valacyclovir only *reduces* transmission, it doesn't stop it entirely. Accordingly, patients must continue to use condoms, and must abstain from sex at times when the infection is active.

95... PROCTITIS

Sexually acquired proctitis (inflammation of the rectum) results primarily from receptive anal intercourse. Symptoms include anorectal pain, tenesmus (painful straining at stool), and rectal discharge. Usual causative organisms are *N. gonorrhoeae*, *C. trachomatis*, *T. pallidum*, and HSV. The preferred treatment is *ceftriaxone* (125 mg IM once) plus *doxycycline* (100 mg PO twice daily for 7 days).

95... VENEREAL WARTS

Genital and perianal warts are caused by human papillomaviruses. Characteristics and treatment of these warts are discussed in [Chapter 104](#).

95.13.1 KEY POINTS

- *Chlamydia trachomatis* is the most common cause of bacteria STDs in the United States.
- Two drugs—doxycycline and azithromycin—are preferred agents for treating chlamydial infection in nonpregnant adolescents and adults.
- Gonorrhea is caused by *Neisseria gonorrhoeae*, a gram-negative diplococcus often referred to as the gonococcus.
- Gonorrhea is the second most common STD in the United States.
- Two cephalosporins—cefixime and ceftriaxone—are preferred drugs for gonorrhea.
- Syphilis is caused by the spirochete *Treponema pallidum*.
- Penicillin G is the drug of choice for treating all stages of syphilis.
- Bacterial vaginosis can be caused by multiple microorganisms, including *Gardnerella vaginalis*, *Mycoplasma hominis*, and various anaerobes.
- In nonpregnant women, bacterial vaginosis can be treated orally with metronidazole, or intravaginally with metronidazole or clindamycin.
- In pregnant women, bacterial vaginosis is treated only with oral medication, either metronidazole or clindamycin.
- Most genital herpes infections are caused by herpes simplex virus type 2. Over 45 million Americans have this STD.
- Genital herpes can be treated with three drugs: acyclovir, famciclovir, and valacyclovir. These agents do not eliminate the virus, but they can reduce symptoms and shorten the duration of viral shedding and pain.

⁹⁶CHAPTER 95 Antiseptics and Disinfectants

Antiseptics and disinfectants are locally acting drugs that are toxic to microorganisms. These agents are used to reduce acquisition and transmission of infection. Drugs suitable for antiseptics and disinfection cannot be used internally because of toxicity.

^{96.1}GENERAL CONSIDERATIONS

^{96.1.1}Terminology

The terms *antiseptic* and *disinfectant* are not synonymous. In common usage, the term *antiseptic* is reserved for agents *applied to living tissue*. *Disinfectants* are preparations *applied to objects*. As a rule, agents used as disinfectants are too harsh for application to living tissue. Disinfectants are employed most frequently to decontaminate surgical instruments and to cleanse hospitals and other medical facilities. Most uses of antiseptics are prophylactic. For example, antiseptics are used to cleanse the hands of medical personnel; they are applied to the patient's skin prior to invasive procedures (eg, surgery, insertion of needles); and they are used to bathe neonates. Rarely, antiseptics are employed to treat an existing local infection. However, in most cases, established infections are best treated with a systemic antimicrobial drug.

Several related terms may need clarification. *Sterilization* indicates complete destruction of all microorganisms. In contrast, *sanitization* implies only that contamination has been reduced to a level compatible with public health standards. A *germicide* is a drug that *kills* microorganisms. Germicides may be divided into subcategories: *bactericides*, *virucides*, *fungicides*, and *amebicides*. In contrast to a germicide, a *germistatic drug* is one that decreases the growth and replication of microorganisms, but does not kill them.

^{96.1.2}Properties of an Ideal Antiseptic

The ideal antiseptic, like any other ideal drug, should be safe, effective, and selective. The preparation should be germicidal (rather than germistatic) and should have a broad spectrum of antimicrobial activity: The drug should kill bacteria and their spores, along with viruses, protozoa, yeasts, and fungi. Effects should have a rapid onset and long duration. Development of microbial resistance should be low. The drug should have no harmful effects on humans: It should not produce local injury, impair healing, or produce systemic toxicity following topical application. Lastly, the drug should not cause stains and should be devoid of offensive odor. No antiseptic has all of these properties.

96.1.3 Time Course of Action

Toxicity to microorganisms is determined in part by duration of exposure to an antiseptic or disinfectant. Some agents act more quickly than others. For example, ethanol (70% solution) reduces cutaneous bacterial count by 50% in just 36 seconds. In contrast, benzalkonium chloride (at a dilution of 1:1000) requires 7 minutes to produce the same effect. Because such differences exist, effective use of antiseptics and disinfectants requires that healthcare personnel understand the exposure requirements of these agents.

96.1.4 Use of Antiseptics to Treat Established Local Infection

In the past, topical agents were used routinely to treat established local infection. Today, *systemic* anti-infective drugs are the treatment of choice. Why? First, systemic agents are more effective than topical drugs. Second, systemic agents don't damage inflamed or abraded tissue. Experience has shown that antiseptics do little to reduce infection in wounds, cuts, and abrasions. This lack of efficacy is attributed to poor penetration to the site of infection, and to diminished activity in the presence of wound exudates. Although of limited value for *established* local infection, antiseptics are quite useful as *prophylaxis*: When applied properly, antiseptics can help cleanse wounds and decrease microbial contamination.

96.1.5 Using Antiseptics and Disinfectants Most Effectively

The principal value of antiseptics and disinfectants derives from their ability to prevent contamination of the patient by microorganisms in the *environment*: It appears that antiseptics applied directly to the *patient* contribute relatively little to prophylaxis against infection (except in patients who are neutropenic). A number of clinical studies support this conclusion. In one study, over 5000 preoperative patients were bathed with hexachlorophene. Although this treatment greatly reduced the concentration of surface bacteria, it had no effect on the incidence of postoperative infection. Similarly, in a study of patients who had undergone cardiothoracic surgery, it was found that most postoperative infections were caused by organisms not present at the site of incision. From these studies and others, we can conclude that infections are caused primarily by environmental microorganisms rather than by organisms living on the skin of the patient. Consequently, use of antiseptics by nurses, physicians, and others who contact the patient offers much greater protection than does application of antiseptics to the patient. Patients also benefit greatly by the rigorous use of disinfectants to decontaminate surgical supplies and medical buildings.

1140

1141

96.2 PROPERTIES OF INDIVIDUAL ANTISEPTICS AND DISINFECTANTS

Antiseptics and disinfectants derive from a variety of chemical families, ranging from alcohols to iodine compounds to phenols. The various antiseptics and disinfectants differ from one another with respect to mechanism of action, time course, and antimicrobial spectrum. In almost all cases, the drugs employed as disinfectants are not used for antiseptics and vice versa. The more commonly employed antiseptics and disinfectants are listed in [Table 95-1](#). For each drug, the table indicates chemical family and clinical use (antiseptics, disinfection, or both).

96.2.1 Alcohols

96.2.1.1 Ethanol

Ethanol (ethyl alcohol) is an effective virucide and kills most common pathogenic bacteria as well. The drug is inactive against bacterial spores, and its activity against fungi is erratic. Bactericidal effects result from precipitating bacterial proteins and dissolving membranes. Ethanol can enhance the effects of several other antimicrobial preparations (eg, chlorhexidine, benzalkonium chloride).

Ethanol is employed almost exclusively for *antiseptics*. The most frequent uses are hand washing by hospital staff and cleansing the skin prior to needle insertion and minor surgery. Because it has limited activity against bacterial spores and fungi, ethanol is not a good disinfectant.

Optimal bacterial kill requires that ethanol be present in the proper concentration. The drug is most effective at a concentration of 70%. Higher concentrations are *less* active.

Ethanol should not be applied to open wounds. Why? Because the drug can increase tissue damage and, by causing coagulation of proteins, can form a mass under which bacteria can thrive.

Ethanol for antiseptics is available in three formulations: solutions, gels, and foams. No one formulation has been proved more effective than the others.

96.2.1.2 Isopropanol

Isopropanol (isopropyl alcohol) is employed primarily as an antiseptic. When applied in concentrations greater than 70%, isopropanol is somewhat more germicidal than ethanol. Like ethanol, isopropanol can increase the effects of other antiseptics. Isopropanol promotes local

vasodilation and can thereby increase bleeding from needle punctures and incisions.

Isopropanol is available in concentrations ranging from 70% to 100%.

96.2.2 Aldehydes

96.2.2.1 Glutaraldehyde

Glutaraldehyde [Cidex] is lethal to all microorganisms; the drug kills bacteria, bacterial spores, viruses, and fungi. Antimicrobial effects result from cross-linking and precipitating proteins.

Glutaraldehyde is used to disinfect and sterilize surgical instruments and other medical supplies, including respiratory and anesthetic equipment, catheters, and thermometers. The drug is too harsh for antiseptic use. To completely eliminate bacterial spores, instruments and equipment must be immersed in glutaraldehyde for at least 10 hours, and all blood should be

removed first. Glutaraldehyde is most active at alkaline pH. However, under alkaline conditions, glutaraldehyde eventually becomes inactive owing to gradual polymerization. Consequently, alkaline solutions of glutaraldehyde are active for only 2 to 4 weeks. Glutaraldehyde should be used with adequate ventilation because fumes can irritate the respiratory tract.

1141

1142

TABLE 95-1 Antiseptics and Disinfectants: Chemical Category and Application

Chemical Category	Drug	Application	
		Antisepsis	Disinfection
Alcohols	Ethanol	✓	
	Isopropanol	✓	
Aldehydes	Glutaraldehyde		✓
	Formaldehyde		✓
Iodine Compounds	Iodine tincture	✓	
	Iodine solution	✓	
Iodophors	Povidone-iodine	✓	✓
Chlorine Compounds	Oxychlorosene	✓	
	Sodium hypochlorite	✓	✓
Phenolic Compound	Hexachlorophene	✓	
Miscellaneous Agents	Chlorhexidine	✓	
	Thimerosal	✓	
	Hydrogen peroxide		✓
	Benzalkonium chloride	✓	✓

96.2.2.2 Formaldehyde

Formaldehyde kills bacteria, bacterial spores, viruses, and fungi. Like glutaraldehyde, formaldehyde is too harsh for application to the skin. Accordingly, use is limited to disinfection and sterilization of equipment and instruments. For two reasons, formaldehyde is less desirable than glutaraldehyde. First, formaldehyde acts slowly: Destruction of bacterial spores may take 2 to 4 days. Second, because it is more volatile than glutaraldehyde, formaldehyde tends to cause more respiratory irritation. As with glutaraldehyde, blood should be removed before instruments and equipment are sterilized.

96.2.3 Iodine Compounds: Iodine Solution and Iodine Tincture

Iodine was first employed as an antiseptic more than 160 years ago. Despite the introduction of numerous other drugs, iodine remains one of our most widely used germicidal agents. The drug

is extremely effective, having the ability to kill all known bacteria, fungi, protozoa, viruses, and yeasts. Additional assets are low cost and low toxicity.

The composition of iodine solution and iodine tincture is very similar. Iodine *solution* consists of 2% elemental iodine and 2.4% sodium iodide in water. Iodine *tincture* contains the same amounts of elemental iodine and sodium iodide and also contains 47% ethanol. The ethanol enhances the antimicrobial activity of iodine tincture.

The germicidal activity of iodine tincture and iodine solution is due only to *free* (dissolved) elemental iodine. In both the tincture and the solution, the concentration of free elemental iodine is very low—about 0.15%—owing to the poor solubility of iodine in water. Because only free iodine is active, most of the elemental iodine and all of the sodium iodide present in both iodine tincture and iodine solution do not contribute *directly* to microbicidal activity. However, these components do contribute *indirectly* by serving as reservoirs from which free elemental iodine can be released.

Iodine tincture and iodine solution are employed primarily for antiseptics of the skin, a use for which they are the most effective agents available. When the skin is *intact*, iodine *tincture* is preferred. This preparation is commonly employed to cleanse the skin prior to IV injection and withdrawal of blood for microbial culture. For treatment of *wounds* and *abrasions*, iodine *solution* should be employed. (Because alcohol is an irritant, iodine tincture is less appropriate for application to broken skin.)

96.2.4 Iodophors: Povidone-Iodine

An iodophor is simply a complex composed of elemental iodine plus a solubilizing agent. Antimicrobial effects derive from release of free iodine. The intact iodophor is inactive.

Povidone-iodine is an iodophor composed of elemental iodine plus povidone, an organic polymer that increases the solubility of the iodine. Povidone-iodine has no antimicrobial activity of its own. Rather, it serves as a reservoir from which elemental iodine can be released. Free elemental iodine is the active germicide. The concentration of free iodine achieved with application of povidone-iodine is lower than that produced with application of iodine tincture or iodine solution. Hence, povidone-iodine is less effective than these other iodine preparations.

Povidone-iodine is employed primarily for prophylaxis of postoperative infection. Additional uses include hand washing, surgical scrubbing, and preparing the skin prior to invasive procedures (eg, surgery, aspiration, injection). In addition, povidone-iodine is employed to sterilize equipment, although superior disinfectants are available.

The drug is supplied in a variety of formulations (ointments, solutions, aerosols, gels). It is also impregnated in swabs, sponges, and wipes. Trade names include ACU-dyne, Betadine, and Operand.

96.2.5 Chlorine Compounds

Chlorine is lethal to a wide variety of microbes, and is active both as elemental chlorine and as hypochlorous acid, which is formed by reaction of chlorine with water. Chlorine is used extensively to sanitize water supplies and swimming pools. However, because of physical properties that make working with chlorine difficult, chlorine itself is rarely used clinically. Instead, chlorine-containing compounds that release hypochlorous acid are employed.

96.2.5.1 Oxychlorosene Sodium

Oxychlorosene sodium [Clorpactin WCS 90] is a complex mixture of hypochlorous acid with alkylphenyl sulfonates. Antimicrobial effects derive from releasing hypochlorous acid. Oxychlorosene is lethal to bacteria, yeasts, fungi, viruses, molds, and spores. The preparation is employed as a topical antiseptic and can be especially useful for treating localized infection caused by drug-resistant microbes. Oxychlorosene is also employed as an antiseptic for surgical prophylaxis and to irrigate and cleanse fistulas, sinus tracts, wounds, and empyemas (pus-filled cavities).

96.2.5.2 Sodium Hypochlorite

Sodium hypochlorite kills bacteria, spores, fungi, protozoa, and viruses. Undiluted (5%) solutions are employed commonly as household bleach. These concentrated solutions are too irritating for application to human tissue. For antiseptic use, dilute (0.5%) solutions are employed. These preparations can be used to irrigate wounds and to cleanse and deodorize necrotic tissue. To minimize local irritation, solutions of sodium hypochlorite should be rinsed off promptly. A 1% solution can be used to sterilize equipment. Solutions of sodium hypochlorite are unstable and must be prepared fresh before each use.

96.2.6 Phenols

The family of phenolic compounds consists of phenol itself and several phenol derivatives. Following its introduction in 1867, phenol rapidly became both the antiseptic and disinfectant of choice. Today, use of phenol for antiseptic purposes is rare. However, the drug is still employed in some hospitals for disinfection. One member of the phenol family—hexachlorophene—is discussed below.

96.2.6.1 Hexachlorophene

96.2.6.1.1 Actions.

Hexachlorophene is *bacteriostatic*, not bactericidal. The drug is quite active against gram-positive bacteria—the bacteria found most frequently on the skin. However, hexachlorophene has little or no effect on gram-negative bacteria. In fact, when used on a regular basis, hexachlorophene encourages overgrowth with gram-negative organisms. (By killing off gram-positive bacteria, hexachlorophene makes conditions more conducive to gram-negative growth.)

96.2.6.1.2 Uses.

In the past, hexachlorophene was used for hand cleansing by healthcare personnel. However, the drug is no longer an accepted ingredient for hand disinfectants, and should not be used in the clinical setting.

96.2.6.1.3 Adverse Effects.

Hexachlorophene can be absorbed through intact skin and mucous membranes. Absorption through denuded areas can be especially significant. If absorbed in sufficient amounts, hexachlorophene causes central nervous system stimulation. Responses range from confusion to twitching to seizures. Deaths have occurred. To minimize systemic toxicity, hexachlorophene should not be applied extensively to burns, wounds, cuts, or mucous membranes. In addition, total body bathing, especially of infants, should be avoided. For bathing infants, chlorhexidine is safer and more effective.

1142

96.2.6.1.4 Preparations.

1143

Hexachlorophene is available only by prescription. The drug is supplied in solution and emulsion under the trade name pHisoHex. A foam formulation, sold as Septisol, is no longer available.

96.2.7 Miscellaneous Agents

96.2.7.1 Chlorhexidine

96.2.7.1.1 Actions and Uses.

Chlorhexidine is an important surgical antiseptic. The drug is fast acting and lethal to most gram-positive and gram-negative bacteria. Virucidal activity is lacking. Antibacterial effects are reduced somewhat in the presence of soap, blood, and pus. Chlorhexidine that remains on the skin after rinsing is sufficient to exert continuing germicidal effects. Chlorhexidine is used for preoperative preparation of the skin and as a surgical scrub, hand-wash preparation, and wound cleanser. It is also the preferred agent for preventing infection associated with insertion of central lines. In patients with gingivitis and periodontitis, chlorhexidine is used as an oral rinse.

96.2.7.1.2 Adverse Effects.

Chlorhexidine is very safe. Even with routine preoperative use, local adverse effects are rare. Inadvertent IV injection has been reported twice: in one patient, hemolysis occurred; in the other, no ill effects were observed.

96.2.7.1.3 Preparations.

Chlorhexidine gluconate (0.5%, 2%, 4%) is formulated in combination with isopropanol (4% or 70%). Trade names include Exidine-2 Scrub, Dyna-Hex 2 Skin Cleanser, Hibistat Germicidal Hand Rinse, and Hibiclens.

96.2.7.2 Hydrogen Peroxide

Hydrogen peroxide is an excellent disinfectant and sterilizing agent, but is useless as an antiseptic. The entity in hydrogen peroxide solution responsible for antimicrobial effects is the hydroxyl free radical. These free radicals are destroyed when hydrogen peroxide is acted upon by catalase, an enzyme found in all tissues. Hence, contact with tissue terminates germicidal actions. The only benefit resulting from application of hydrogen peroxide to wounds derives from liberation of oxygen (by the reaction with catalase), which causes frothing that is sufficient to loosen debris and thereby facilitate cleansing. The principal use of hydrogen peroxide is disinfection and sterilization of instruments. A 3% to 6% solution is employed.

96.2.7.3 Thimerosal

Thimerosal is an organic compound that contains 49% mercury, the active antimicrobial factor. Thimerosal has only weak bacteriostatic and fungistatic properties, and hence does not kill bacteria or fungi. Antimicrobial actions are reduced in the presence of blood and tissue proteins. Thimerosal is less effective than ethanol. Use on large areas of denuded skin may yield systemic toxicity from absorption of mercury. Poisoning from thimerosal ingestion can be treated with dimercaprol (see [Chapter 108](#)). Thimerosal has been employed to irrigate wounds and prepare the skin prior to surgery. It has also been employed as an antiseptic for the eyes, nose, throat, and genitourinary tract. However, given that thimerosal has low efficacy and a significant potential for harm, it would seem that safer, more effective agents would be preferable. Trade names are Mersol and Aeroaid.

Until recently, thimerosal was widely used as a preservative in vaccines. However, owing to concerns about a possible (albeit unproved) link between thimerosal and autism, nearly all vaccines used by Americans are now devoid of this agent. The only exception is the influenza vaccine.

96.2.7.4 Benzalkonium Chloride

96.2.7.4.1 Actions.

Benzalkonium chloride (BAC) is an organic quaternary ammonium compound that has antimicrobial and detergent properties. BAC is active against many gram-positive and gram-negative bacteria as well as some fungi, protozoa, and viruses. The drug is relatively *inactive* against *Mycobacterium tuberculosis*, *Clostridium*, and other spore-forming bacteria. Germicidal effects result from disruption of membranes, and are enhanced by ethanol. BAC is inactivated by soaps and organic material. BAC is slow acting compared with iodine.

96.2.7.4.2 Antiseptic Uses.

BAC is employed for preoperative preparation of the skin and mucous membranes; as a surgical scrub; as an antiseptic for abrasions and minor wounds; as a vaginal douche; and for irrigation of the eyes, body cavities, and genitourinary tract. Because BAC is inactivated by soap, all soap must be removed by rinsing with water and 70% alcohol prior to BAC application. Concentrated solutions of BAC can cause severe local injury. Hence, care must be taken to use solutions of appropriate dilution. For several reasons (limited antimicrobial spectrum, lack of rapid action, potential for toxicity, availability of superior agents), there seems to be little to recommend BAC for antiseptic use.

96.2.7.4.3 Disinfectant Use.

Immersion in BAC solution is employed for sterile storage of instruments and supplies. Adsorption of BAC onto porous material can significantly reduce the concentration of BAC in solutions. To ensure continuing efficacy, solutions should be changed (or at least replenished with BAC) on a regular basis.

96.2.7.4.4 Preparations and Dosage.

BAC is supplied in concentrated (17%) and dilute (1:750) solution. Trade names include Benza and Zephiran. Recommended dilutions are 1:750 (for application to intact skin and to minor wounds and abrasions); 1:2000 to 1:5000 (for application to mucous membranes and diseased or seriously damaged skin); and 1:750 to 1:5000 (for storage of instruments and supplies).

96.3 HAND HYGIENE FOR HEALTHCARE WORKERS

Effective hand hygiene is the single most important factor in preventing the spread of infection in healthcare settings. Each year, an estimated 2 million patients in the United States acquire an infection while in a hospital; about 90,000 of them die as a result. Patients can also acquire infections in other settings, including clinics, dialysis centers, and long-term care facilities. In all of these places, the leading cause of infection spread is the transfer of pathogens from one patient to another on the hands of healthcare workers (HCWs). Accordingly, the best way to reduce new infections in these settings is to improve hand hygiene.

Traditionally, HCWs cleaned their hands with soap and water. Unfortunately, this technique has several drawbacks: it takes considerable time, requires a sink and hand-washing supplies, and promotes skin irritation and dryness. As a result, adherence tends to be poor.

In 2002, the Centers for Disease Control and Prevention (CDC) issued guidelines designed to improve hand-hygiene practices among HCWs and to reduce transmission of pathogenic microorganisms to patients and personnel in healthcare settings. A central recommendation in the guidelines is the use of *alcohol-based handrubs*, rather than soap and water, for *routine* hand antisepsis. There are four reasons for this recommendation:

- *Accessibility*—Handrubs don't require a sink or towels, and hence are more accessible than washing with soap and water.
- *Time savings*—Using a handrub is much faster than washing with soap and water. All you do is apply the handrub to the palm of one hand, and then rub your hands together until they are

dry. The CDC estimates that, during an 8-hour shift, an intensive care unit nurse would save about 1 hour by using a handrub instead of soap and water.

- *Lessened skin damage*—Today's alcohol-based handrubs contain emollients and moisturizers, and hence don't irritate or dry the skin like soap and water do.
- *Greater efficacy*—Alcohol-based handrubs reduce the number of bacteria on the skin more effectively than does washing with soap and water.

Studies have shown that, because of these advantages, switching from soap and water to an alcohol-based handrub can significantly improve adherence among HCWs.

1143

1144

It is important to note that alcohol-based handrubs have limitations. First, they can't remove dirt or organic material. Accordingly, when the hands are visibly soiled, soap and water must be used first. Second, alcohol lacks residual killing power. For routine clinical practice, this lack is no concern. However, under certain conditions—including infectious disease outbreaks and performance of invasive procedures—an antiseptic that does have residual effects (eg, chlorhexidine), should be used.

[Table 95-2](#) lists the antimicrobial spectrum, speed of onset, and unique properties of some antiseptic agents used in hand-hygiene products.

96.3.1 Specific CDC Hand-Hygiene Recommendations

Major recommendations from the CDC hand-hygiene guidelines are presented below. Each recommendation is categorized on the basis of existing scientific data, theoretical rationale, applicability, and economic impact. The five categories employed are defined as follows:

Category IA—Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies

Category IB—Strongly recommended for implementation and supported by certain experimental, clinical, or epidemiologic studies and a strong theoretical rationale

Category IC—Required for implementation, as mandated by federal or state regulation or standard

Category II—Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale

No recommendation/Unresolved issue—Practices for which insufficient evidence or no consensus regarding efficacy exists

96.3.1.1 Indications for Hand Washing and Hand Antisepsis

- When hands are visibly dirty or contaminated with proteinaceous material or are visibly soiled with blood or other body fluids, wash hands with either a non-antimicrobial soap and water or an antimicrobial soap and water (IA).
- If hands are not visibly soiled, use an alcohol-based handrub for routinely decontaminating hands in all clinical situations described in italics below (IA). Alternatively, wash hands with an antimicrobial soap and water in all clinical situations described in italics below (IB).
- *Decontaminate hands before having direct contact with patients (IB).*
- *Decontaminate hands before donning sterile gloves when inserting a central intravascular catheter (IB).*
- *Decontaminate hands before inserting indwelling urinary catheters, peripheral vascular catheters, or other invasive devices that do not require a surgical procedure (IB).*
- *Decontaminate hands after contact with a patient's intact skin (eg, when taking a pulse or blood pressure, and lifting a patient) (IB).*
- *Decontaminate hands after contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings if hands are not visibly soiled (IA).*
- *Decontaminate hands if moving from a contaminated body site to a clean body site during patient care (II).*
- *Decontaminate hands after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient (II).*
- *Decontaminate hands after removing gloves (IB).*
- Before eating and after using a restroom, wash hands with a non-antimicrobial soap and water or with an antimicrobial soap and water (IB).
- Antimicrobial-impregnated wipes (ie, towelettes) may be considered as an alternative to washing hands with nonantimicrobial soap and water. Because they are not as effective as alcohol-based handrubs or washing hands with an antimicrobial soap and water for

1144

1145

reducing bacterial counts on the hands of HCWs, they are not a substitute for using an alcohol-based handrub or antimicrobial soap (IB).

TABLE 95-2 Antimicrobial Spectrum and Characteristics of Hand-Hygiene Antiseptic Agents*

Group	Gram-Positive Bacteria	Gram-Negative Bacteria	Mycobacteria	Fungi	Viruses	Speed of Action	Comments
Alcohols	+++	+++	+++	+++	+++	Fast	Optimum concentration 60–95%; no persistent activity
Chlorhexidine (2% and 4% aqueous)	+++	++	+	+	+++	Intermediate	Persistent activity; rare allergic reactions
Iodine compounds	+++	+++	+++	++	+++	Intermediate	Causes skin burns; usually too irritating for hand hygiene
Iodophors	+++	+++	+	++	++	Intermediate	Less irritating than iodine; acceptance varies
Phenol derivatives	+++	+	+	+	+	Intermediate	Activity neutralized by nonionic surfactants
<p>From Centers for Disease Control and Prevention: Guideline for hand hygiene in health-care settings: Recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force. MMWR Morb Mortal Wkly Rep 51(RR-16), 2002.</p> <p>+++ excellent, ++ good, but does not include the entire bacterial spectrum, + fair.</p>							

* Hexachlorophene is not included because it is no longer an accepted ingredient of hand disinfectants.

- Wash hands with non-antimicrobial soap and water or with antimicrobial soap and water if exposure to *Bacillus anthracis* is suspected or proven. The physical action of washing and rinsing hands under such circumstances is recommended because alcohols, chlorhexidine, iodophors, and other antiseptic agents have poor activity against spores (II).
- No recommendation can be made regarding the routine use of non-alcohol-based handrubs for hand hygiene in healthcare settings (Unresolved issue).

96.3.1.2 Hand-Hygiene Technique

- When decontaminating hands with an alcohol-based handrub, apply product to palm of one hand and rub hands together, covering all surfaces of hands and fingers, until hands are dry (IB). Follow the manufacturer's recommendations regarding the volume of product to use.
- When washing hands with soap and water, wet hands first with water, apply an amount of product recommended by the manufacturer to hands, and rub hands together vigorously for at least 15 seconds, covering all surfaces of the hands and fingers. Rinse hands with water and dry thoroughly with a disposable towel. Use towel to turn off the faucet (IB). Avoid using hot water, because repeated exposure to hot water may increase the risk of dermatitis (IB).
- Liquid, bar, leaflet, or powdered forms of plain soap are acceptable when washing hands with a non-antimicrobial soap and water. When bar soap is used, soap racks that facilitate drainage and small bars of soap should be used (II).
- Multiple-use cloth towels of the hanging or roll type are not recommended for use in healthcare settings (II).

96.3.1.3 Surgical Hand Antisepsis

- Remove rings, watches, and bracelets before beginning the surgical hand scrub (II).
- Remove debris from underneath fingernails using a nail cleaner under running water (II).
- Surgical hand antisepsis using either an antimicrobial soap or an alcohol-based handrub with persistent activity is recommended before donning sterile gloves when performing surgical procedures (IB).
- When performing surgical hand antisepsis using an antimicrobial soap, scrub hands and forearms for the length of time recommended by the manufacturer, usually 2 to 6 minutes. Long scrub times (eg, 10 minutes) are not necessary (IB).
- When using an alcohol-based surgical hand-scrub product with persistent activity, follow the manufacturer's instructions. Before applying the alcohol solution, prewash hands and forearms with a non-antimicrobial soap and dry hands and forearms completely. After application of the alcohol-based product as recommended, allow hands and forearms to dry thoroughly before donning sterile gloves (IB).

96.3.1.4 Other Aspects of Hand Hygiene

- Do not wear artificial fingernails or extenders when having direct contact with patients at high risk (eg, those in intensive care units or operating rooms) (IA).
- Keep natural nail tips less than ¼-inch long (II).
- Wear gloves when contact with blood or other potentially infectious materials, mucous membranes, and nonintact skin could occur (IC).
- Remove gloves after caring for a patient. Do not wear the same pair of gloves for the care of more than one patient, and do not wash gloves between uses with different patients (IB).
- Change gloves during patient care if moving from a contaminated body site to a clean body site (II).
- No recommendation can be made regarding wearing rings in healthcare settings (Unresolved issue). (*Note:* A 2003 study demonstrated that wearing a ring reduced the efficacy of hand cleansing.)

96.3.1.5 Administrative Measures Regarding Hand Hygiene

- As part of a multidisciplinary program to improve hand-hygiene adherence, provide HCWs with a readily accessible alcohol-based handrub product (IA).
- To improve hand-hygiene adherence among personnel who work in areas in which high workloads and high intensity of patient care are anticipated, make an alcohol-based handrub available at the entrance to the patient's room or at the bedside, in other convenient locations, and in individual pocket-sized containers to be carried by HCWs (IA).

96.3.1.5.1

KEY POINTS

- Because the various antiseptics and disinfectants require different durations of exposure to be effective, you must know the time course of action of the specific agent you are working with.
- Although antiseptics can help prevent *development* of a local infection, systemic anti-infective drugs are preferred for treating an *established* local infection.

- Washing with antiseptics by nurses, physicians, and others who contact patients will do more to protect patients from infection than will application of antiseptics to patients themselves.
- For routine hand antisepsis, alcohol-based handrubs are preferred to soap and water.

⁹⁷CHAPTER 96 Anthelmintics

Helminths are parasitic worms, and *anthelmintics* are the drugs used against them. Helminthiasis (worm infestation) is the most common affliction of humans, affecting more than 2 billion people worldwide. The intestine is a frequent site of infestation. Other sites include the liver, lymphatic system, and blood vessels. Infestation is frequently asymptomatic. However, infestation with some parasites can cause severe complications. Helminthiasis is most prevalent where sanitation is poor. Cleanliness greatly reduces infestation risk.

Treatment of helminthiasis is not always indicated. Most parasitic worms do not reproduce in the human body. Hence, in the absence of reinfestation, many infections subside on their own as adult worms die. Accordingly, treatment may be optional. In countries where providers and medication are readily available, drug therapy is definitely indicated. However, in less fortunate locales, several factors—cost of medication, limited medical facilities, and high probability of reinfestation—may render individual treatment impractical. In these places, preventative measures, such as improved hygiene and elimination of carriers, may be the most valuable interventions.

In approaching the anthelmintic drugs, we begin by reviewing classification of the parasitic worms. Next we briefly discuss the characteristics of the more common helminthic infestations. After this, we discuss preferred drugs for treatment.

^{97.1} CLASSIFICATION OF PARASITIC WORMS

The most common parasitic worms belong to three classes: Nematoda (roundworms), Cestoda (tapeworms), and Trematoda (flukes). Nematodes belong to the phylum Nematelminthes. Cestodes and trematodes belong to the phylum Platyhelminthes (flat worms).

^{97.1.1} Nematodes (Roundworms)

Parasitic nematodes can be subdivided into two groups: (1) those that infest the intestinal lumen and (2) those that inhabit tissues. There are five major species of intestinal nematodes. Their common names are giant roundworm, pinworm, hookworm, whipworm, and threadworm. Official names (eg, *Ascaris lumbricoides*) are listed in [Table 96-1](#). Two types of nematodes invade tissues: (1) pork roundworms (responsible for trichinosis) and (2) filariae. The three species of filariae encountered most commonly are listed in [Table 96-1](#).

^{97.1.2} Cestodes (Tapeworms)

Three species of cestodes infest humans. Common names for these parasites are beef tapeworm, pork tapeworm, and fish tapeworm. Their official names appear in [Table 96-1](#).

97.1.3 Trematodes (Flukes)

Five species of trematodes infest humans. These organisms fall into four groups having the following common names: blood fluke, liver fluke, intestinal fluke, and lung fluke. Official names of the five species belonging to these groups are given in [Table 96-1](#).

97.2 HELMINTHIC INFESTATIONS

This section describes the major characteristics of infestation by specific helminths. These infestations can differ with respect to anatomic site and danger to the host. Infestations also differ with respect to the drugs employed for treatment (see [Table 96-1](#) for a summary).

The name applied to an infestation is based on the official name of the invading organism. For example, infestation with the giant roundworm, whose official name is *Ascaris lumbricoides*, is referred to as *ascariasis*.

In the discussion below, the helminthic infestations are grouped in four categories: (1) nematode infestations of the intestine, (2) nematode infestations of extraintestinal sites, (3) cestode infestations, and (4) trematode infestations.

97.2.1 Nematode Infestations (Intestinal)

97.2.1.1 Ascariasis (Giant Roundworm Infestation).

Ascariasis is the most prevalent helminthic infestation. Worldwide, one of every three people is affected. Adult worms inhabit the small intestine. Ascariasis is usually asymptomatic. However, serious complications can result if worms migrate into the pancreatic duct, bile duct, gallbladder, or liver. In addition, if infestation is extremely heavy, intestinal blockage may occur. Because of these potential hazards, ascariasis should always be treated. Drugs of choice are *mebendazole*, *albendazole*, and *ivermectin*.

97.2.1.2 Enterobiasis (Pinworm Infestation).

Enterobiasis is the most common helminthic infestation in the United States. Adult pinworms inhabit the ileum and large intestine. Their life span is approximately 2 months. Although usually asymptomatic, enterobiasis may cause intense perineal itching in some patients. Serious complications are rare. Drugs of choice are *mebendazole*, *albendazole*, and *pyrantel*. Because enterobiasis is readily transmitted, all family members of an infected individual should be treated simultaneously.

97.2.1.3 Ancylostomiasis and Necatoriasis (Hookworm Infestation).

Hookworm infestation is most common in rural areas where hygiene is poor and people go barefoot. Adult hookworms attach to the wall of the small intestine and suck blood. As a result, infestation is associated with chronic blood loss and progressive anemia. Symptomatic anemia is most likely in menstruating women and undernourished individuals. Nausea, vomiting, and abdominal pain may accompany the infestation. *Mebendazole*, *albendazole*, and *pyrantel* are treatments of choice.

97.2.1.4 Trichuriasis (Whipworm Infestation).

Trichuriasis is extremely common, affecting about 1 billion people worldwide. Larvae and adult worms inhabit the large intestine. Mature worms may live for 10 years or more. The disease is usually devoid of symptoms. However, when the worm burden is very large, rectal prolapse may occur. Patients with severe infestation require therapy. *Mebendazole* is the treatment of choice.

1146

1147

TABLE 96-1 Drugs of Choice for Parasitic Worms

Parasitic Organism			
Worm Class	Common Name	Official Name	Drugs of Choice
Nematodes (roundworms): intestinal	Giant roundworm	<i>Ascaris lumbricoides</i>	Mebendazole or albendazole or ivermectin
	Pinworm	<i>Enterobius vermicularis</i>	Mebendazole or albendazole or pyrantel
	Hookworm	<i>Ancylostoma duodenale, Necator americanus</i>	Mebendazole or albendazole or pyrantel
	Whipworm	<i>Trichuris trichiura</i>	Mebendazole
	Threadworm	<i>Strongyloides stercoralis</i>	Ivermectin
Nematodes (roundworms): extraintestinal	Pork roundworm	<i>Trichinella spiralis</i>	Albendazole*
	Filariae	<i>Wuchereria bancrofti, Brugia malayi</i>	Diethylcarbamazine†
Cestodes (tapeworms)		<i>Onchocerca volvulus</i>	Ivermectin
	Beef tapeworm	<i>Taenia saginata</i>	Praziquantel*
	Pork tapeworm	<i>Taenia solium</i>	
	Fish tapeworm	<i>Diphyllobothrium latum</i>	
Trematodes (flukes)	Blood fluke	<i>Schistosoma</i> species	Praziquantel
	Intestinal fluke	<i>Fasciolopsis buski</i>	
	Lung fluke	<i>Paragonimus westermani</i>	
	Liver flukes	<i>Fasciola hepatica</i> (sheep liver fluke)	Triclabendazole
		<i>Clonorchis sinensis</i> (Chinese liver fluke)	Praziquantel or albendazole*

* Not approved by the Food and Drug Administration for this indication.

† Available from the Centers for Disease Control and Prevention (CDC).

97.2.1.5 Strongyloidiasis (Threadworm Infestation).

Strongyloidiasis is common in the southern United States. Larval and adult threadworms inhabit the small intestine. The disease can be very dangerous, although symptoms are usually absent. Mild infestation may cause abdominal pain and occasional diarrhea. Severe infestation can cause vomiting, massive diarrhea, dehydration, electrolyte imbalance, and secondary bacteremia. Death has occurred. Affected individuals should always be treated. *Ivermectin* is the treatment of choice.

97.2.2 Nematode Infestations (Extraintestinal)

97.2.2.1 Trichinosis (Pork Roundworm Infestation).

Trichinosis is acquired by eating undercooked pork that contains encysted larvae of *Trichinella spiralis*. Adult worms reside in the intestine, whereas larvae migrate to skeletal muscle and become encysted. Some encysted larvae live for years; others die and calcify within months. Symptoms of trichinosis include GI upset, fever, muscle pain, and sore throat. Potentially lethal complications (heart failure, meningitis, neuritis) arise in some patients. *Albendazole* is the drug of choice for killing adult worms and migrating larvae. However, this agent may not be active against larvae that have become encysted. *Prednisone* (a glucocorticoid) is given to reduce inflammation during larval migration.

97.2.2.2 Wuchereriosis and Brugianis (Lymphatic Filarial Infestation).

Wuchereria bancrofti and *Brugia malayi* are filarial nematodes that invade the lymphatic system. Infestation with either organism can cause severe complications. When infestation is heavy, lymphatic obstruction occurs, resulting in *elephantiasis* (usually of the scrotum or legs). In addition, “filarial fever” may develop. Symptoms include chills, fever, headache, nausea, vomiting, constipation, and lymphadenitis. The drug of choice for killing both filarial species is *diethylcarbamazine*.

97.2.2.3 Onchocerciasis (River Blindness).

Onchocerca volvulus is a filarial nematode found in streams and rivers of Mexico, Guatemala, northern South America, and equatorial Africa. The parasite is transmitted to humans by the bite of certain flies. Heavy infestation with *O. volvulus* causes dermatologic and ophthalmic symptoms. Dermatologic manifestations include subcutaneous nodules (filled with adult worms) and persistent pruritic dermatitis. Ocular lesions, caused by the infiltration and death of

microfilariae, result in optic neuritis, optic atrophy, and then blindness. The drug of choice for treating onchocerciasis is *ivermectin*.

97.2.3 Cestode Infestations

97.2.3.1 Taeniasis (Beef and Pork Tapeworm Infestation).

Taeniasis is acquired by eating undercooked beef or pork that contains tapeworm larvae. Adult tapeworms live attached to the wall of the small intestine. Infestation is usually asymptomatic. Taeniasis is treated with *praziquantel*.

97.2.3.2 Diphyllbothriasis (Fish Tapeworm Infestation).

Diphyllobothriasis is acquired by ingestion of undercooked fish that is infested with tapeworm larvae. Adult worms inhabit the ileum. Infestation is usually devoid of symptoms. Worms can be killed with *praziquantel*.

97.2.4 Trematode Infestations

97.2.4.1 Schistosomiasis (Blood Fluke Infestations).

The term *schistosomiasis* refers to infestation with blood flukes of any species (eg, *Schistosoma mansoni*, *S. japonicum*). Specific snails serve as intermediate hosts for these flukes. Schistosomiasis cannot be acquired in the continental United States because the appropriate snails are not indigenous.

Schistosomiasis has an acute and a chronic phase. The acute phase subsides in 3 to 4 months. Symptoms during this phase include lymphadenopathy, fever, anorexia, malaise, muscle pain, and rash. During the chronic phase, schistosomes take up residence in the vascular system, primarily in veins of the intestines and liver. This late infestation can produce intestinal polyposis, hepatosplenomegaly, and portal hypertension. For either the acute or the chronic stage, *praziquantel* is the treatment of choice.

97.2.4.2 Fascioliasis (Liver Fluke Infestation).

Fascioliasis is caused by two liver flukes: *Fasciola hepatica* (sheep liver fluke) and *Clonorchis sinensis* (Chinese liver fluke). Both parasites inhabit the biliary tract. Symptoms (anorexia, mild fever, fatigue, aching in the region of the liver) are delayed for 1 to 3 months.

1147

1148

TABLE 96-2 First-Choice Anthelmintic Drugs: Target Organisms and Dosages

Generic Name [Trade Name]	Target Organism	Adult and Pediatric Dosages
Mebendazole [Vermox]	Giant roundworm	100 mg 2 times/day for 3 days or 500 mg once
	Whipworm	
	Hookworm	
	Pinworm	100 mg; repeat in 2–3 weeks if needed
Albendazole [Albenza]	Giant roundworm	400 mg once
	Hookworm	
	Pork roundworm	400 mg 2 times/day for 8–14 days
	Pinworm	400 mg; repeat in 2–3 weeks if needed
Triclabendazole	Chinese liver fluke	10 mg/kg/day for 7 days
	Sheep liver fluke	10 mg/kg once or twice
Pyrantel [Pin-Rid, others]	Hookworm	11 mg/kg (max 1 gm) for 3 days
	Pinworm	11 mg/kg (max 1 gm); repeat in 2 weeks
Praziquantel [Biltricide]	Beef tapeworm	5–10 mg/kg once
	Pork tapeworm	
	Fish tapeworm	
	Blood flukes	20 mg/kg 2 times/day for 1 day
	Intestinal fluke	25 mg/kg 3 times/day for 1 day
	Chinese liver fluke	25 mg/kg 3 times/day for 2 days
Diethylcarbamazine* [Hetrazan]	Lung fluke	2 mg/kg 3 times/day for 12 days
	<i>Wuchereria bancrofti</i>	
	<i>Brugia malayi</i>	
	<i>Loa loa</i>	
Ivermectin [Stromectol]	Threadworm	200 mcg/kg/day for 1 or 2 days
	Giant roundworm	150–200 mcg/kg once
	<i>Onchocerca volvulus</i>	150 mcg/kg every 6–12 months until asymptomatic

* Available from the Centers for Disease Control and Prevention.

Liver flukes differ in drug sensitivity. The preferred drug for use against *F. hepatica* is *triclabendazole* (a veterinary anthelmintic). The preferred drugs for use against *C. sinensis* are *praziquantel* and *albendazole*.

97.2.4.3 Fasciolopsiasis (Intestinal Fluke Infestation).

Fasciolopsiasis is most common in Southeast Asia. Adult worms inhabit the small intestine. The disease is usually asymptomatic. However, some people experience ulcer-like pain; some develop constipation or diarrhea; and, in the presence of massive infestation, bowel obstruction may occur, requiring surgery for clearance. *Praziquantel* is the treatment of choice.

97.3 DRUGS OF CHOICE FOR HELMINTHIASIS

The major anthelmintic drugs are considered below. These agents differ from one another in antiparasitic spectra: some are active against several worms; others are more selective. Because of these differences, it is important to identify the invading organism so that the most appropriate drug can be chosen. [Table 96-2](#) lists the major anthelmintic drugs and indicates the parasites against which each is most effective. Although the discussion that follows is limited to drugs of choice, be aware that additional anthelmintics are available.

97.3.1 Mebendazole

97.3.1.1 Target Organisms.

Mebendazole [Vermox] is a drug of choice for most *intestinal roundworms*. This agent clears infestation with *pinworms*, *hookworms*, *whipworms*, and *giant roundworms*. Because of its relatively broad spectrum of action, mebendazole is especially useful for treatment of mixed infestations.

97.3.1.2 Mechanism of Action.

Mebendazole prevents uptake of glucose by susceptible intestinal worms. Glucose deprivation results in immobilization followed by slow death. Since the worms die slowly, up to 3 days may elapse between initiating treatment and complete clearance of parasites. Mebendazole does not influence glucose uptake or utilization by humans.

97.3.1.3 Pharmacokinetics.

Only a small fraction (5% to 10%) of orally administered mebendazole is absorbed, and this fraction undergoes rapid metabolism. Consequently, plasma levels of mebendazole remain low.

97.3.1.4 Adverse Effects.

Systemic effects are rare at usual doses, perhaps because the drug is so poorly absorbed. In patients with massive parasitic infestations, transient abdominal pain and diarrhea may occur.

Relatively low doses are embryotoxic and teratogenic in rats. However, these effects have not been observed in dogs, sheep, or horses. Limited experience with mebendazole in pregnant women has shown no increase in spontaneous abortion or fetal malformation. Nonetheless, *it is recommended that pregnant women avoid this drug, especially during the first trimester.*

97.3.1.5 Preparations, Dosage, and Administration.

Mebendazole [Vermox] is available in 100-mg tablets for oral administration. The tablets may be chewed, crushed, or swallowed whole. Dosages are summarized in [Table 96-2](#).

97.3.2 Albendazole

97.3.2.1 Target Organisms.

Albendazole [Albenza] is active against many cestode and nematode parasites, including larval forms of *Taenia solium* and *Echinococcus granulosus*. In the United States, the drug is approved only for (1) parenchymal *neurocysticercosis* caused by larval forms of the pork tapeworm, *T. solium*; and (2) *cystic hydatid disease* of the liver, lung, and peritoneum caused by larval forms of the dog tapeworm, *E. granulosus*. However, despite lack of formal approval, albendazole is considered a drug of choice for infestation with giant roundworms, hookworms, pinworms, Chinese liver flukes, and pork roundworms, the cause of trichinosis.

1148

1149

97.3.2.2 Mechanism of Action.

Albendazole inhibits polymerization of tubulin, and thereby prevents formation of cytoplasmic microtubules. As a result, microtubule-dependent uptake of glucose is prevented.

97.3.2.3 Pharmacokinetics.

Albendazole is poorly absorbed from the GI tract, owing largely to low solubility in water. Absorption is enhanced by administration with a fatty meal. Following absorption, albendazole is rapidly converted to albendazole sulfoxide, its active form. Albendazole sulfoxide is distributed widely to body fluids and tissues, and is excreted in the bile. The half-life is 8 to 12 hours.

97.3.2.4 Adverse Effects.

Albendazole is generally well tolerated. Mild to moderate *liver impairment* has occurred in 16% of patients, as indicated by elevation of liver transaminases in plasma. Liver function should be assessed before treatment and periodically thereafter. Albendazole is teratogenic in animals and hence *should not be used during pregnancy*. If pregnancy occurs, the drug should be discontinued immediately.

97.3.2.5 Preparations, Dosage, and Administration.

Albendazole [Albenza] is supplied in 200-mg tablets for oral use. Dosages for giant roundworms, hookworms, pinworms, pork roundworms, and Chinese liver flukes are shown in [Table 96-2](#).

For *neurocysticercosis* or *cystic hydatid disease*, each dose is 400 mg (for patients greater than 60 kg) or 7.5 mg/kg (for patients less than 60 kg). The dosing schedule for cystic hydatid disease is two doses twice daily with meals for 8 to 30 days. Dosing for neurocysticercosis is done in three consecutive cycles, each consisting of two doses twice daily with meals for 28 days followed by 14 days with no drug.

97.3.3 Thiabendazole

97.3.3.1 Target Organisms.

At one time, thiabendazole [Mintezol] was the drug of choice for *threadworms*. However, ivermectin is now preferred.

97.3.3.2 Pharmacokinetics.

Thiabendazole undergoes rapid absorption and metabolism. Most of each dose is excreted in the urine as metabolites within 24 hours.

97.3.3.3 Adverse Effects.

The incidence of adverse reactions is high: As many as one-third of patients become incapacitated for several hours. The most common effects are GI distress (anorexia, nausea, vomiting) and neurologic reactions (dizziness, drowsiness). Because of the potential for reduced alertness, patients should avoid driving and other hazardous activities. Hepatotoxicity with jaundice has been reported. Accordingly, thiabendazole should not be used by patients with liver dysfunction.

97.3.3.4 Preparations, Dosage, and Administration.

Thiabendazole [Mintezol] is available in 500-mg chewable tablets and an oral suspension (100 mg/mL). Patients should be instructed to chew the tablets thoroughly. Gastrointestinal discomfort can be reduced by administering thiabendazole with food.

97.3.4 Pyrantel

97.3.4.1 Target Organisms.

Pyrantel [Pin-Rid, Pin-X, Reese's Pinworm] is active against *intestinal nematodes*. The drug is an alternative to mebendazole or albendazole for infestations with *hookworms* or *pinworms*.

97.3.4.2 Mechanism of Action.

Pyrantel is a depolarizing neuromuscular blocking agent that causes spastic paralysis of intestinal parasites. The paralyzed worms are cleared in the feces.

97.3.4.3 Pharmacokinetics.

Pyrantel is poorly absorbed, and plasma levels remain low. Most of an administered dose is excreted unchanged in the feces.

97.3.4.4 Adverse Effects.

Serious reactions are rare. The most common effects are GI reactions (nausea, vomiting, diarrhea, stomach pain, cramps). Possible central nervous system effects include dizziness, drowsiness, headache, and insomnia.

97.3.4.5 Preparations, Dosage, and Administration.

Pyrantel pamoate is supplied in soft-gel capsules (180 mg) and liquid formulations (50 mg/mL) for oral use. The entire prescribed dose should be taken at one time. Dosages for intestinal nematodes are given in [Table 96-2](#).

97.3.5 Praziquantel

97.3.5.1 Target Organisms.

Praziquantel [Biltricide] is very active against *flukes* and *cestodes* (tapeworms), and is the drug of choice for *tapeworms*, *schistosomiasis*, and other *fluke infestations*.

97.3.5.2 Mechanism of Action.

Praziquantel is readily absorbed by helminths. At low therapeutic concentrations, the drug produces spastic paralysis, causing detachment of worms from body tissues. At high therapeutic concentrations, praziquantel disrupts the integument of the worms, rendering the parasites vulnerable to lethal attack by host defenses.

97.3.5.3 Pharmacokinetics.

Praziquantel is rapidly absorbed from the GI tract. The drug undergoes extensive hepatic metabolism. Metabolites are excreted in the urine. The half-life is short (about 1.5 hours).

97.3.5.4 Adverse Effects.

Praziquantel is relatively free of toxicity. Transient headache and abdominal discomfort are the most frequent reactions. Drowsiness may occur, and hence patients should avoid driving and other hazardous activities.

97.3.5.5 Preparations, Dosage, and Administration.

Praziquantel [Biltricide] is available in 600-mg tablets for oral administration. Tablets should be swallowed intact. Dosages for tapeworm and fluke infestations are presented in [Table 96-2](#).

97.3.6 Diethylcarbamazine

97.3.6.1 Target Organisms.

Diethylcarbamazine [Hetrazan] is the drug of choice for *filarial infestations*. The drug destroys microfilariae of *W. bancrofti*, *B. malayi*, and *Loa loa*. In addition, it kills adult females of these species.

97.3.6.2 Mechanism of Action.

Diethylcarbamazine has two antifilarial actions. First, it reduces muscular activity, thereby causing parasites to be dislodged from their site of attachment. Second, by altering the surface properties of the parasites, it renders the organisms more vulnerable to attack by host defenses.

97.3.6.3 Pharmacokinetics.

Diethylcarbamazine is readily absorbed and undergoes rapid and extensive metabolism. Metabolites are excreted in the urine.

97.3.6.4 Adverse Effects.

Adverse effects caused directly by diethylcarbamazine are minor (headache, weakness, dizziness, nausea, vomiting). Indirect effects, occurring secondary to death of the parasites, can be more serious. These include rashes, intense itching, encephalitis, fever, tachycardia, lymphadenitis, leukocytosis, and proteinuria. Fortunately, these reactions are transient, lasting just a few days—and can be minimized by pretreatment with glucocorticoids.

97.3.6.5 Preparations, Dosage, and Administration.

Diethylcarbamazine citrate [Hetrazan] is supplied in 50-mg tablets for oral use. The drug is available from the Centers for Disease Control and Prevention (CDC). Dosages for filarial infestations are presented in [Table 96-2](#).

97.3.7 Ivermectin

97.3.7.1 Target Organisms.

Ivermectin [Stromectol] is active against many *nematodes*. Currently, the drug has two approved indications: *onchocerciasis* (a major cause of blindness worldwide) and intestinal *strongyloidiasis*. Ivermectin is active against the tissue microfilariae of *O. volvulus* (the cause of onchocerciasis), but not against the adult form. As discussed in [Chapter 99](#), ivermectin can also be used to kill *mites* and *lice*, although these parasites are not approved targets. In addition to its use in humans, ivermectin is used widely in veterinary medicine.

97.3.7.2 Mechanism of Action.

Ivermectin disrupts nerve traffic and muscle function in target parasites. How? By opening chloride channels on the cell surface, which allows chloride ions to rush into nerve and muscle cells. The resultant hyperpolarization of these cells causes paralysis followed by death. Host cells are not affected because ivermectin is selective for chloride channels in parasites.

97.3.7.3 Pharmacokinetics.

Ivermectin is administered orally and achieves peak plasma levels in 4 hours. Distribution to the central nervous system is poor. The drug is metabolized in the liver and excreted in the feces. Less than 1% of each dose appears in urine. The half-life is 16 hours.

97.3.7.4 Adverse Effect: Mazotti Reaction.

The Mazotti reaction occurs in patients treated for *onchocerciasis*. Principal symptoms are pruritus (28%), rash (23%), fever (23%), lymph node tenderness (13%), and bone and joint pain (9%). The apparent cause is an allergic and inflammatory response to the death of microfilariae. Mazotti-type reactions do not occur in patients treated for strongyloidiasis.

97.3.7.5 Use in Pregnancy.

Ivermectin is teratogenic in mice, rats, and rabbits. Cleft palate is the most common effect. There are no adequate data on teratogenesis in humans. Until more is known, *ivermectin should be avoided during pregnancy*.

97.3.7.6 Preparations, Dosage, and Administration.

Ivermectin [Stromectol] is available in 3-mg tablets. Instruct patients to take the drug with water. For *strongyloidiasis*, the adult and pediatric dosage is 200 mcg/kg/day for 1 or 2 days. For *onchocerciasis* (river blindness), the adult and pediatric dosage is 150 mcg/kg/day, repeated every 6 to 12 months until symptoms are gone.

1149

97.3.7.6.1

KEY POINTS

- Because each anthelmintic drug is active against a limited range of worms, we must select the appropriate drug for the infestation to be treated.
- Many worm infestations are both asymptomatic and self-limited, and hence drug therapy can be optional. When cost is not an issue, treatment is clearly indicated. However, in countries where funds are limited, preventative public health measures directed at improved hygiene and elimination of carriers may be more cost-effective than treating each infested individual.
- With the exception of thiabendazole, the drugs discussed in this chapter are generally devoid of serious adverse effects.

1150

⁹⁸CHAPTER 97 Antiprotozoal Drugs I: Antimalarial Agents

Malaria is a parasitic disease caused by protozoa of the genus *Plasmodium*. With the exception of tuberculosis, malaria kills more people than any other infectious disease. About 300 million people are afflicted each year, and over 1 million die. Seventy-five percent of deaths occur in sub-Saharan Africa, almost entirely among young children. In the United States, of the 1200 cases reported annually, almost all were acquired outside the country.

Large-scale attempts to eradicate the disease have achieved only partial success. Eradication programs have been directed at the malarial parasite as well as the *Anopheles* mosquito, the insect that transmits malaria to humans. Failure to produce complete control has resulted largely from development of drug resistance by both the parasite and the mosquito. The incidence of malaria is rising in regions where it had once been suppressed. There remains a great need for safe, effective, and affordable agents capable of killing the malaria parasite and its mosquito carrier. Vaccines against malaria, which are in development, would be the ideal way to manage the disease.

In approaching the antimalarial drugs, we begin by reviewing the life cycle of the malaria parasite. After that we discuss the two major subtypes of malaria: falciparum malaria and vivax malaria. Next, we consider basic principles of treatment, focusing on therapeutic objectives and drug selection. Lastly, we discuss the pharmacology of the antimalarial drugs.

^{98.1} LIFE CYCLE OF THE MALARIA PARASITE

In order to understand the actions and specific applications of antimalarial drugs, we must first understand the life cycle of the malaria parasite. As indicated in [Figure 97-1](#), the cycle takes place in two hosts: humans and the female *Anopheles* mosquito. Asexual reproduction occurs in humans. Sexual reproduction occurs in the mosquito.

The human phase begins when *sporozoites* are injected into the bloodstream by a feeding *Anopheles* mosquito. The sporozoites invade hepatocytes (liver cells), where they either (1) multiply and transform into *merozoites* or (2) transform into *hypnozoites* and lie dormant. The process of merozoite production, which takes 12 to 26 days (depending upon the species of parasite), is referred to as the pre-erythrocytic or exoerythrocytic phase of the life cycle. Following their release from hepatocytes, merozoites infect erythrocytes. Within the erythrocyte, each parasite differentiates and divides, becoming first a trophozoite and then a multinucleated schizont. The schizont then evolves into new merozoites. This asexual reproductive process takes 2 to 3 days, after which red blood cells burst, releasing new merozoites into the blood. The new merozoites then infect fresh erythrocytes, thereby establishing an escalating cycle of red cell invasion and

lysis. Each time the erythrocytes rupture, they release pyrogenic (fever-inducing) agents, which cause the repeating episodes of fever that characterize malaria.

Sexual reproduction begins with the formation of *gametocytes*, which differentiate from some of the merozoites in red blood cells (see [Figure 97-1](#)). Following their release from red cells, gametocytes enter a female *Anopheles* mosquito when she ingests blood while feeding. Within the mosquito, the gametocytes differentiate into mature forms, after which fertilization takes place. The resulting zygote then produces sporozoites, thus completing sexual reproduction.

98.2 TYPES OF MALARIA

Malaria is caused by four different species of *Plasmodium*. In this chapter, we limit discussion to the two species encountered most: *Plasmodium vivax* and *Plasmodium falciparum*. Malaria caused by either species is characterized by high fever, chills, and profuse sweating. However, despite similarity of symptoms, these forms of malaria are very different—especially with regard to severity of symptoms, relapse, and drug resistance. These and other differences are summarized in [Table 97-1](#).

1151

1152

Figure 97-1 Life cycle of the malaria parasite.

98.2.1 Vivax Malaria

Vivax malaria, caused by *P. vivax*, is the most common form of malaria. Fortunately, the disease is relatively mild and usually self-limiting. Because drug resistance by *P. vivax* is relatively uncommon, symptoms can be readily suppressed with medication.

Infection begins when the host is inoculated with *P. vivax* sporozoites. After 26 days, merozoites emerge from hepatocytes and begin their attack on erythrocytes. Symptoms of malaria (eg, chills, fever, sweating) commence as infected erythrocytes rupture, releasing pyrogens and other substances into the blood. Symptoms peak, decline, and peak again every 48 hours in response to cyclic reinfection and cell lysis. This cycle continues until terminated by drugs or by acquired immunity. Unfortunately, relapse is likely following termination of the acute attack. Why?

Because with *P. vivax* infection, dormant parasites (hypnozoites) remain in the liver.

Periodically, these hypnozoites evolve into merozoites, undergo release into the blood, and start the erythrocytic cycle anew. Relapse becomes less frequent with the passage of time, and, after 2 or more years, ceases entirely. Relapse can be stopped with drugs that kill hypnozoites.

98.2.2 Falciparum Malaria

Malaria caused by *P. falciparum* is less common than malaria caused by *P. vivax*, but is much more severe. In the absence of treatment, the disease kills about 10% of its victims. Making matters worse, many strains of *P. falciparum* are drug resistant. Unlike the symptoms of vivax malaria, which peak every 48 hours, symptoms of falciparum malaria occur at irregular intervals. The erythrocytic cycle of *P. falciparum* can destroy up to 60% of circulating red blood cells, resulting in profound anemia and weakness. The hemoglobin released from these cells causes the urine to darken, giving rise to the term *black-water fever*. Falciparum malaria can produce serious complications, including pulmonary edema, hypoglycemia, and toxic encephalopathy, characterized by confusion, coma, and convulsions. When treated immediately, falciparum malaria usually responds well. However, if treatment is delayed (by as little as 1 or 2 days), the disease may progress rapidly to irreversible shock and death. In contrast to infection with *P. vivax*, infection with *P. falciparum* does not relapse. Why? Because *P. falciparum* does not form hypnozoites. As a result, once the erythrocytic forms have been eliminated, the patient is parasite free.

1152

1153

TABLE 97-1 Comparison of Vivax Malaria and Falciparum Malaria

Characteristics	Type of Malaria	
	Vivax Malaria	Falciparum Malaria
Causative organism	<i>Plasmodium vivax</i>	<i>Plasmodium falciparum</i>
Frequency of infection	More common	Less common
Latency of symptoms	26 days	12 days
Intensity of symptoms	Mild	Severe
Timing of febrile paroxysms	Every 2 days	Irregular
Probability of relapse	High	None
Drug resistance	Uncommon	Common

98.3 PRINCIPLES OF ANTIMALARIAL THERAPY

98.3.1 Therapeutic Objectives

Drug responsiveness of the malaria parasite changes as the parasite goes through its life cycle. The *erythrocytic* forms are killed with relative ease, whereas the *exoerythrocytic* (hepatic) forms are much harder to kill—and *sporozoites* do not respond to drugs at all. Because of these differences, antimalarial therapy has three separate objectives: (1) treatment of an acute attack (clinical cure), (2) prevention of relapse (radical cure), and (3) prophylaxis (suppressive therapy). Because sporozoites are insensitive to available drugs, drugs cannot prevent primary infection of the liver.

98.3.1.1 Treatment of an Acute Attack.

Clinical cure is accomplished with drugs that are active against erythrocytic forms of the malaria parasite. By eliminating parasites from red blood cells, the erythrocytic cycle is stopped and symptoms cease. For patients with vivax malaria, clinical cure will not prevent relapse, because hypnozoites remain in the liver. However, for patients with falciparum malaria, successful treatment of the acute attack prevents further episodes.

98.3.1.2 Prevention of Relapse.

People infected with *P. vivax* harbor dormant parasites in the liver. In order to prevent relapse, a drug that can kill these hepatic forms must be taken. The use of drugs to eradicate hepatic *P. vivax* is referred to as *radical cure*. Since reinfection by a mosquito bite is a virtual certainty as

long as one remains in a malariaendemic region, radical cure is often postponed until departure from the area.

98.3.1.3 Prophylaxis.

Persons anticipating travel to an area where malaria is endemic should take antimalarial medication for prophylaxis. Although drugs cannot prevent primary infection of the liver, they *can* prevent infection of erythrocytes. Hence, although the parasite may be present, symptoms are avoided. Because prophylactic treatment prevents only symptoms but not invasion of the liver, such treatment is often referred to as *suppressive therapy*.

Nondrug measures can help greatly to prevent infection. Since *Anopheles* mosquitoes only bite between dusk and dawn, clothing that covers as much skin as possible should be worn during this time. A diethyltoluamide (DEET)—containing insect repellent should be applied to skin that remains exposed. Sleeping under mosquito netting that has been impregnated with an insecticide (eg, permethrin) further reduces the risk of a bite.

98.3.2 Drug Selection

Selection of antimalarial drugs is based largely on two factors: (1) the goal of treatment and (2) drug resistance of the causative strain of *Plasmodium*. Drugs of choice for treatment and prophylaxis are discussed below and summarized in [Table 97-2](#).

98.3.2.1 Treatment of Acute Attacks.

For *mild to moderate* malaria, *oral* therapy is employed. Chloroquine is the drug of choice for an acute attack caused by chloroquine-sensitive strains of *P. falciparum* or *P. vivax*. As a rule, a 3-day course of treatment produces clinical cure. For strains of *P. falciparum* or *P. vivax* that are chloroquine resistant, quinine is a drug of first choice, combined with either doxycycline, tetracycline, or clindamycin. Malarone, a fixed-dose combination of atovaquone plus proguanil, is an effective alternative. Mef-loquine may also be used, but is considered less desirable owing to concerns about neuropsychiatric effects.

For *severe* malaria caused by *P. falciparum* or *P. vivax*, *parenteral* therapy is required. In the United States, only one drug—quinidine gluconate—is approved by the Food and Drug Administration (FDA) for parenteral use in malaria. When used for severe malaria, IV quinidine should be combined with doxycycline, tetracycline, or clindamycin. An alternative to quinidine, known as artesunate, is recommended by the World Health Organization.

Pharmacology for Nursing Care, 7th Edition

Unfortunately, artesunate is not commercially available here, although it can be obtained by special request from the Centers for Disease Control and Prevention (CDC).

98.3.2.2 Prevention of Relapse.

The agent of choice for preventing relapse of vivax malaria is primaquine, a drug that is highly active against the hepatic forms of *P. vivax*. For falciparum malaria, no treatment is needed, since relapse does not occur following clinical cure.

98.3.2.3 Prophylaxis.

Selection of drugs for prophylaxis is based on the drug sensitivity of the plasmodial species found in the region to which travel is intended. In regions where chloroquine-sensitive strains are endemic, chloroquine is the preferred drug for prophylaxis. In regions of chloroquine resistance, either mefloquine, doxycycline, or atovaquone/proguanil may be used. Recommendations regarding preferred drugs for prophylaxis in specific countries are available online at www.cdc.gov/malaria/travel/index.htm.

TABLE 97-2 Drugs of Choice for Malaria*

Therapeutic Objective	Plasmodium falciparum		Plasmodium vivax	
	Chloroquine Sensitive	Chloroquine Resistant	Chloroquine Sensitive	Chloroquine Resistant
Treatment of a <i>moderate</i> attack	Chloroquine	Atovaquone/proguanil or Quinine <i>plus either</i> doxycycline, tetracycline, or clindamycin or Mefloquine	Chloroquine	Same as <i>P. falciparum</i>
Treatment of a <i>severe</i> attack	For <i>P. falciparum</i> or <i>P. vivax</i> , use <i>intravenous</i> quinidine <i>plus either</i> doxycycline, tetracycline, or clindamycin [†]			
Relapse prevention	NA [‡]	NA [‡]	Primaquine	Primaquine
Prophylaxis	Chloroquine	Atovaquone/proguanil, meflo- quine, or doxycycline	Chloroquine	Same as <i>P. falciparum</i>

- * All drugs are given orally except where noted otherwise.
- † Intravenous artesunate, available from the Centers for Disease Control and Prevention, is an alternative to IV quinidine.
- ‡ Not applicable. Malaria caused by *P. falciparum* does not relapse following successful treatment of the acute attack.

98.4 PHARMACOLOGY OF THE MAJOR ANTIMALARIAL DRUGS

98.4.1 Chloroquine

98.4.1.1 Actions and Use.

Chloroquine [Aralen] is the most generally useful antimalarial drug. Because of its high activity against erythrocytic forms of the parasite, chloroquine is the drug of choice for mild to moderate acute attacks caused by sensitive strains of *P. vivax* or *P. falciparum*. Chloroquine is also the drug of choice for prophylaxis (suppressive therapy).

Chloroquine is not active against *exoerythrocytic* forms of the malaria parasite. Hence, the drug is unable to prevent primary infection by *P. vivax* or *P. falciparum*. Nor is it able to prevent relapse of vivax malaria, which is caused by emergence of dormant hypnozoites.

Several mechanisms have been proposed to explain the lethal effects of chloroquine on erythrocytic malaria parasites. The most likely is that chloroquine prevents the organism from converting heme to nontoxic metabolites. (Heme, a potentially toxic compound, is produced by the parasite as it digests hemoglobin in the host's red blood cells.) Chloroquine concentrates in parasitized erythrocytes, and this may explain the selective actions against erythrocytic forms of *Plasmodium*.

98.4.1.2 Pharmacokinetics.

Chloroquine is rapidly and completely absorbed from the GI tract. A substantial fraction of absorbed drug is deposited in certain tissues, including the lungs, spleen, liver, and kidneys. Slow release from these sites helps maintain therapeutic levels. Hence, when used for prophylaxis, chloroquine can be administered just once a week. Excretion is primarily nonrenal.

98.4.1.3 Adverse Effects.

Because the doses required for prophylaxis are low, and because the higher doses required for treatment are taken only briefly, chloroquine rarely causes serious adverse effects. When employed to treat an acute attack, chloroquine may cause visual disturbances, pruritus, headache, and GI effects (abdominal discomfort, nausea, diarrhea). Gastrointestinal effects can be minimized by taking the drug with meals. Because chloroquine concentrates in the liver, caution is needed in patients with hepatic disease.

98.4.1.4 Routes of Administration.

Chloroquine may be administered orally or IM. Oral therapy is preferred. Intramuscular administration is employed only when emesis precludes oral treatment or when infection is especially severe.

98.4.1.5 Preparations, Dosage, and Administration.

Chloroquine phosphate [Aralen] is available in tablets (250 and 500 mg) for oral administration. A parenteral formulation—chloroquine hydrochloride—is no longer available in the United States.

For *prophylaxis* of malaria, the adult dosage is 500 mg once a week. The pediatric dosage is 8.3 mg/kg once a week. Treatment should commence 1 week before expected exposure to malaria and should continue 4 weeks after leaving the endemic region.

To *treat an acute attack*, the adult dosage is 1 gm of chloroquine phosphate initially, followed by doses of 500 mg given 6, 24, and 48 hours later. The pediatric dosage is 17 mg/kg initially, followed by doses of 8 mg/kg given 6, 24, and 48 hours later.

98.4.2 Primaquine

98.4.2.1 Actions and Use.

Primaquine is highly active against *hepatic* forms of *P. vivax*, but not against erythrocytic forms. The drug is used to eradicate *P. vivax* from the liver, thereby preventing relapse. The mechanism of plasmodial kill has not been determined.

98.4.2.2 Pharmacokinetics.

Primaquine is well absorbed following oral administration. Absorbed drug is rapidly metabolized to products of low antimalarial activity. Metabolites are excreted in the urine.

98.4.2.3 Adverse Effect: Hemolysis.

The most serious and frequent effect is hemolysis, which can develop in patients whose red blood cells are deficient in glucose-6-phosphate dehydrogenase (G6PD). This deficiency is an inherited trait, occurring most commonly in black populations and in darker skinned whites, such as Sardinians, Greeks, Iranians, and Sephardic Jews. When possible, patients suspected of G6PD deficiency should be screened for the trait before treatment. During primaquine therapy, periodic blood counts should be performed. Also, the urine should be monitored (darkening indicates the presence of hemoglobin). If severe hemolysis develops, primaquine should be discontinued.

1154

1155

98.4.2.4 Preparations, Dosage, and Administration.

Primaquine phosphate is supplied in 26.3-mg tablets (containing 15 mg of primaquine base) and as a powder (5, 25, 100, and 500 gm). Dosing should be done with food to minimize GI distress. For radical cure of vivax malaria, the adult dosage is 30 mg of primaquine base daily for 2 weeks. The pediatric dosage is 0.5 mg/kg of primaquine base daily for 2 weeks.

98.4.3 Quinine

At one time, quinine [Qualaquin] was the only drug available to treat malaria. Today, quinine has been largely replaced by more effective and less toxic agents (eg, chloroquine). However, quinine still has an important role: treatment of chloroquine-resistant malaria. Quinine occurs naturally in the bark of the cinchona tree. Commercial preparations are derived from this source.

98.4.3.1 Actions and Use.

Quinine is active against erythrocytic forms of *Plasmodium* but has little effect on sporozoites and hepatic forms. Like chloroquine, quinine concentrates in parasitized red blood cells and may be selective against erythrocytic parasites for this reason. Also like chloroquine, quinine kills plasmodia by causing heme to accumulate within the parasites.

The principal application of quinine is malaria caused by chloroquine-resistant *P. falciparum*. Because quinine is not highly active, adjunctive therapy with another agent is required. Recommended adjuncts are doxycycline, tetracycline, and clindamycin.

98.4.3.2 Pharmacokinetics.

Quinine is well absorbed from the GI tract, even in patients with diarrhea. The drug undergoes hepatic metabolism followed by excretion in the urine. Plasma levels of quinine fall rapidly after stopping treatment.

98.4.3.3 Adverse Effects.

At usual therapeutic doses, quinine frequently causes mild *cinchonism*, a syndrome characterized by tinnitus (ringing in the ears), headache, visual disturbances, nausea, and diarrhea. The prescriber should be notified if these symptoms develop. Because of its adverse effects on vision and hearing, quinine is contraindicated for patients with optic neuritis or tinnitus.

Like primaquine, quinine can cause *hemolysis* in patients with G6PD deficiency, and hence is contraindicated for these people. All patients using the drug should be monitored for hemolytic anemia.

Intravenous administration may cause *hypotension* and *acute circulatory failure*. To minimize risk, IV quinine should be diluted and injected slowly. Patients should be switched to oral medication as soon as possible.

Quinine has *quinidine-like effects on the heart* and must be used cautiously in patients with atrial fibrillation. By enhancing atrioventricular conduction, quinine can increase passage of atrial impulses to the ventricles, thereby causing a dangerous increase in ventricular rate.

Quinine can cause profound *hypoglycemia*. The mechanism is stimulation of pancreatic beta cells, which causes hyperinsulinemia. Quinine-induced hypoglycemia can be difficult to treat, even with glucose infusions.

Quinine is classified in FDA Pregnancy Risk Category X: The risks of use during pregnancy clearly outweigh any possible benefits. The drug has caused fetal abnormalities, the most common being deafness from damage to the auditory nerve. Quinine can stimulate the uterus, and might thereby induce premature labor. *The drug must not be taken by pregnant women.*

98.4.3.4 Preparations, Dosage, and Administration.

Quinine sulfate [Qualaquin] is available in 324-mg capsules for oral dosing. For chloroquine-resistant falciparum or vivax malaria, the adult dosage is 648 mg every 8 hours for 3 or 7 days. (Duration depends on where the infection was acquired.) The pediatric dosage is 10 mg/kg every 8 hours for 3 or 7 days. In all patients, quinine should be combined with doxycycline, tetracycline, or clindamycin.

98.4.4 Quinidine Gluconate

Quinidine gluconate is the only drug approved by the FDA for parenteral therapy of malaria. As a result, IV quinidine gluconate is the treatment of choice for severe malaria in the United States. Quinidine is the dextroisomer of quinine and shares that drug's antimalarial mechanism and adverse effects. Because severe malaria can rapidly prove fatal, IV quinidine gluconate should be started immediately. The regimen for adults and children consists of a loading dose (10 mg/kg infused over 1 to 2 hours) followed by a continuous infusion (0.02 mg/kg/min) for at least 24 hours, followed in turn by a switch to oral quinine when the patient can tolerate oral therapy. To enhance antiplasmodial effects, both IV quinidine and PO quinine should be accompanied by doxycycline, tetracycline, or clindamycin.

Intravenous quinidine is more cardiotoxic than quinine. Accordingly, patients require continuous electrocardiographic monitoring and frequent monitoring of blood pressure. The risk of cardiotoxicity is increased by bradycardia and by low levels of potassium or magnesium. The infusion should be temporarily slowed if there is significant widening of the QRS complex or prolongation of the QT interval.

Quinidine may not be immediately available. Why? Because many hospitals no longer keep the drug on hand. Why? Because (1) severe malaria is extremely rare in the United States and (2) there are preferred agents for treating dysrhythmias, the only other use for IV quinidine gluconate (see [Chapter 48](#)). In places where the drug is not available, a rapid shipment can be arranged with the manufacturer (Eli Lilly Co).

98.4.5 Mefloquine

98.4.5.1 Actions and Uses.

Mefloquine [Lariam] kills erythrocytic forms of *P. vivax* and *P. falciparum*. The mechanism of action has not been determined, but may be like that of chloroquine. Mefloquine is a drug of

choice for prophylaxis of malaria in regions where chloroquine-resistant *P. falciparum* or *P. vivax* is found. The drug is also used to treat acute attacks by these parasites, although neuropsychiatric effects make it a second-choice agent. Resistance to mefloquine, by an unknown mechanism, may develop quickly.

98.4.5.2 Pharmacokinetics.

Mefloquine is well absorbed following oral administration. The drug undergoes hepatic metabolism and is excreted in the bile and feces. Mefloquine has a prolonged half-life, ranging from 1 to 4 weeks.

98.4.5.3 Adverse Effects.

Adverse effects are dose related. At the low doses employed for prophylaxis, reactions are generally mild (nausea, dizziness, syncope). However, at the higher doses used to treat acute attacks, more intense reactions may occur, including GI disturbances, nightmares, altered vision, and headache. Some of these effects may be indistinguishable from symptoms of malaria.

1155

1156

Toxicity to the central nervous system is a concern. Mefloquine can cause vertigo, confusion, psychosis, and convulsions. The incidence of these neuropsychiatric effects is about 1 in 13,000 at the low doses used for prophylaxis, but increases to 1 in 250 at the doses used for an ongoing attack. High-dose mefloquine should be avoided by people with epilepsy or psychiatric disorders. Patients who develop psychiatric symptoms (hallucinations, depression, suicidal ideation) should discontinue the drug immediately and contact their prescriber for a substitute (eg, quinine plus doxycycline, atovaquone/proguanil).

98.4.5.4 Preparations, Dosage, and Administration.

Mefloquine [Lariam] is available in 250-mg tablets. All doses should be ingested with at least 8 ounces of water.

For *prophylaxis*, the adult dosage is 250 mg once a week. The pediatric dosage is 3 to 5 mg/kg once a week. Dosing should begin 1 week prior to travel to an endemic region and should continue 4 weeks after leaving.

The adult dose for *acute treatment* of *P. falciparum* or *P. vivax* malaria is 750 mg initially followed by 500 mg taken 6 to 12 hours later. The pediatric dosage is 15 mg/kg initially followed by 10 mg/kg taken 6 to 12 hours later.

98.4.6 Atovaquone/Proguanil

98.4.6.1 Activity and Therapeutic Use.

The combination of atovaquone plus proguanil, available as *Malarone*, is highly effective for both the prophylaxis and treatment of malaria caused by chloroquine-resistant plasmodia. Both drugs are active against erythrocytic and exoerythrocytic plasmodial forms, including strains that are resistant to chloroquine, mefloquine, and pyrimethamine/sulfadoxine. In addition to its use in malaria, atovaquone, by itself, has been used for *Pneumocystis pneumonia*.

98.4.6.2 Mechanism of Action.

Atovaquone and proguanil disrupt two separate pathways in pyrimidine synthesis, and thereby suppress DNA replication. Atovaquone has a unique mechanism: disruption of mitochondrial electric transport. No other antimalarial drug works this way. Proguanil is inactive as administered, but gets converted to cycloguanil, its active form. Like pyrimethamine, cycloguanil inhibits plasmodial dihydrofolate reductase, and thereby prevents activation of folic acid. In the absence of useable folic acid, the parasite is unable to make DNA, RNA, and proteins.

98.4.6.3 Pharmacokinetics.

Absorption of atovaquone is low and variable, but can be greatly enhanced by fatty foods. The drug is 99% bound to plasma proteins, has a prolonged half-life (2 to 3 days), and undergoes excretion unchanged in the feces.

In contrast to atovaquone, proguanil is extensively absorbed, both in the presence and absence of food. The drug concentrates in erythrocytes and undergoes hepatic metabolism followed by renal excretion. Its half-life is 12 to 21 hours.

98.4.6.4 Adverse Effects and Interactions.

The combination of atovaquone plus proguanil is generally well tolerated. When atovaquone is used alone, the principal adverse effect is rash, which occurs in 20% to 40% of patients. Other reactions include nausea, vomiting, diarrhea, headache, fever, and insomnia. When proguanil is used alone, the most common side effects are oral ulceration, GI effects, and headache. In addition, the drug may cause hair loss, urticaria, hematuria, thrombocytopenia, and scaling of the soles and palms. Proguanil is considered safe for use during pregnancy; the safety of atovaquone has not been established. Proguanil appears devoid of significant drug interactions.

In contrast, certain drugs, including tetracycline and rif-ampin, can reduce levels of atovaquone by as much as 50%.

98.4.6.5 Preparations, Dosage, and Administration.

Atovaquone combined with proguanil is available in tablets formulated for adults and for children. Adult-strength tablets [Malarone] contain 250 mg of atovaquone and 100 mg of proguanil. Pediatric-strength tablets [Malarone Pediatric] contain 62.5 mg atovaquone and 25 mg proguanil. To enhance absorption, all tablets should be administered with food or milk.

For *prophylaxis* of malaria, dosing begins 1 or 2 days before entering an endemic area and continues for 7 days after leaving. The dosage for adults is 1 adult tablet a day. Dosages for children are based on body weight as follows: 11 to 20 kg, 1 pediatric tablet a day; 21 to 30 kg, 2 pediatric tablets once a day; 31 to 40 kg, 3 pediatric tablets once a day; and over 40 kg, 1 adult tablet daily. Atovaquone/proguanil should not be used for prophylaxis during pregnancy.

For *treatment* of malaria, the dosage for adults is 2 adult tablets twice a day for 3 days. Dosages for children are based on body weight as follows: 11 to 20 kg, 1 *adult* tablet a day for 3 days; 21 to 30 kg, 2 *adult* tablets once a day for 3 days; 31 to 40 kg, 3 *adult* tablets once a day for 3 days; and above 40 kg, 2 *adult* tablets twice a day for 3 days.

98.4.7 Pyrimethamine/Sulfadoxine

98.4.7.1 Therapeutic Use.

In the past, the combination of pyrimethamine and sulfadoxine, sold as *Fansidar*, was used to treat chloroquine-resistant falciparum malaria. However, because of increasing resistance, the CDC no longer recommends the combination. As discussed in [Chapter 98](#), pyrimethamine, in combination with sulfadiazine, remains a treatment of choice for toxoplasmosis.

98.4.7.2 Mechanism of Action.

Pyrimethamine inhibits dihydrofolate reductase, an enzyme that converts folic acid to its active form. Without active folic acid, cells are unable to synthesize DNA, RNA, and proteins. Pyrimethamine rarely disrupts host biochemistry because the concentration of pyrimethamine required to inhibit human dihydrofolate reductase is about 1000 times greater than the concentration needed to inhibit plasmodial dihydrofolate reductase.

The effects of pyrimethamine are potentiated by sulfadoxine, a member of the sulfonamide family. Unlike humans, the malaria parasite is unable to take up preformed folic acid from its

environment. Consequently, the parasite must synthesize folic acid of its own. Sulfadoxine inhibits this process. Hence, the combination of sulfadoxine with pyrimethamine produces a *sequential block* in a critical biochemical pathway. In step one, sulfadoxine inhibits folic acid synthesis, thereby reducing folic acid levels. In step two, pyrimethamine prevents conversion of the reduced pool of folic acid into an active form.

98.4.7.3 Pharmacokinetics.

Pyrimethamine is well absorbed following oral administration. The drug is highly bound to plasma proteins, and hence is eliminated slowly, having a plasma half-life of approximately 4 days. Pyrimethamine undergoes limited hepatic metabolism. Metabolites and parent drug are excreted in the urine.

Sulfadoxine is well absorbed following oral administration and undergoes distribution to all tissues. The drug crosses the placenta with ease. Elimination is primarily renal.

98.4.7.4 Adverse Effects.

At the doses employed for malaria, pyrimethamine produces few adverse effects. However, at high doses, such as those used to treat toxoplasmosis, pyrimethamine can produce symptoms of *folic acid deficiency*. Symptoms result from effects on the bone marrow and the GI mucosa, tissues that have a high percentage of cells undergoing division. Effects on the bone marrow manifest as leukopenia, thrombocytopenia, and anemia. Effects on the GI mucosa manifest as ulcerative stomatitis, atrophic glossitis, pharyngitis, and diarrhea. These responses reverse upon discontinuing treatment, and can be prevented by giving folic acid or folinic acid.

The principal concern with sulfadoxine is hypersensitivity. Mild reactions, such as rash and drug fever, are relatively common. Rarely, the drug causes *Stevens-Johnson syndrome*, a severe reaction with a mortality rate of about 25%. Symptoms include widespread lesions of the skin and mucous membranes, together with fever, malaise, and toxemia. To minimize risk, sulfadoxine should not be given to patients with a history of hypersensitivity to sulfonamides or chemically related drugs, including thiazide diuretics, loop diuretics, and sulfonylurea-type oral hypoglycemics (eg, tolbutamide).

98.4.7.5 Preparations, Dosage, and Administration.

Pyrimethamine and sulfadoxine are available in a fixed-dose combination sold as Fansidar. Tablets contain 25 mg of pyrimethamine and 500 mg of sulfadoxine. To treat an acute attack of chloroquine-resistant malaria, Fansidar, used in conjunction with quinine, is given as a single

dose on the last day of quinine dosing. Fansidar dosages are as follows: adults, 2 to 3 tablets; children 9 to 14 years, 2 tablets; children 4 to 8 years, 1 tablet; children under 4 years, one-half tablet.

98.4.8 Artemether and Artesunate

Artemether [Artemam] and artesunate are the most effective drugs available for multidrug-resistant falciparum malaria. Both agents are derivatives of *artemisinin*, a compound isolated from the sweet wormwood plant, *Artemisia annua*. To be effective, artemether and artesunate must undergo conversion to an active metabolite—*dihydroartemisinin*—which kills plasmodia by releasing free radicals that attack the cell membrane. Kill also requires high concentrations of iron, as are found in red blood cells. Both drugs are widely used in Africa, but are not commercially available in the United States.

1156

1157

Artemether and artesunate are remarkably safe. These drugs can produce *transient* first-degree heart block, as well as a dose-related decrease in red blood cells and neutrophils. They can also prolong coma and promote fever. However, serious or persistent side effects have not been reported.

To prevent development of resistance, artemether and artesunate should not be used alone. Rather, they should be combined with another antimalarial drug. Accordingly, on January 9, 2006, the World Health Organization asked all drug companies to stop selling artemisinin-only products and to replace them with *artemisinin combination therapies* (ACTs). Four ACTs are recommended:

- Artemether/lumefantrine [Coartem]
- Artesunate/mefloquine
- Artesunate/amodiaquine
- Artesunate/pyrimethamine/sulfadoxine

These combinations are indicated only for *treatment* of malaria—not for *prophylaxis*.

The ACT used most widely is a fixed-dose combination of artemether (20 mg) and lumefantrine (120 mg), sold as *Coartem*. Patients take a 3-day course, with dosage based on body weight. The cure rate is about 95%, even against multidrug-resistant *P. falciparum*. To date, there have been no reports of resistance to either component.

Artemisinin derivatives are not licensed for use in the United States. However, one drug—artesunate—*can* be obtained from the CDC, but only if used under the provisions of an Investigational New Drug protocol known as Intravenous Artesunate for Treatment of Severe Malaria in the United States.

98.4.9 Antibacterial Drugs

98.4.9.1 Tetracyclines.

Two members of the tetracycline family—*doxycycline* and *tetracycline*—are used against chloroquine-resistant malaria. Both drugs kill the erythrocytic forms of the malaria parasite, although the rate of kill is slow. Doxycycline is used for prophylaxis and for acute attacks, whereas tetracycline is used for acute attacks only. To treat acute attacks, these drugs are combined with quinine, which acts more quickly than the tetracyclines. All tetracyclines are contraindicated for use by pregnant women and children under 8 years of age. To treat an acute attack, adults take 100 mg of doxycycline twice daily for 7 days, or 250 mg of tetracycline 4 times daily for 7 days. For prophylaxis, adults take 100 mg of doxycycline every day, beginning 2 days before traveling to a malaria-endemic area, and continuing 4 weeks after leaving. The basic pharmacology of the tetracyclines is presented in [Chapter 85](#).

98.4.9.2 Clindamycin.

Clindamycin is active against the erythrocytic forms of the malaria parasite. The drug is used as an adjunct to quinine to treat malaria caused by chloroquine-resistant *P. falciparum* or *P. vivax*. The principal adverse effect is colitis secondary to overgrowth of the bowel with *Clostridium difficile*. The oral dosage for adults and children is 20 mg/kg/day in three divided doses for 7 days.

98.4.9.2.1

KEY POINTS

- There are two principal forms of malaria, one caused by *Plasmodium vivax* and the other by *Plasmodium falciparum*.
- Vivax malaria is more common than falciparum malaria, but falciparum malaria is more severe.
- Drug resistance is common with *P. falciparum* and relatively uncommon with *P. vivax*.

- Plasmodia reside in the liver and erythrocytes. Those in the liver are harder to kill.
- Clinical cure of malaria (ie, elimination of symptoms) results from killing plasmodia in erythrocytes.
- Vivax malaria relapses after clinical cure because hypnozoites remain in the liver. Falciparum malaria does not relapse.
- Chloroquine is the drug of choice for treatment and prophylaxis of malaria caused by chloroquine-sensitive strains of *P. vivax* and *P. falciparum*.
- Atovaquone/proguanil is a treatment of choice for mild to moderate malaria caused by chloroquine-resistant *P. vivax* or *P. falciparum*.
- Intravenous quinidine (combined with doxycycline, tetracycline, or clindamycin) is the treatment of choice for severe malaria caused by *P. vivax* or *P. falciparum*.
- For prophylaxis of chloroquine-resistant malaria, any of three preparations may be used: atovaquone/proguanil, mefloquine, or doxycycline.
- Primaquine, which kills dormant *P. vivax* in the liver, is the drug of choice for preventing relapse of vivax malaria.
- The principal adverse effect of primaquine is hemolytic anemia, which occurs in patients whose red blood cells have a genetically based deficiency of glucose-6-phosphate dehydrogenase.
- The principal adverse effects of quinine are cinchonism (tinnitus, headache, visual disturbances, nausea, vomiting), hemolytic anemia (as with primaquine), and birth defects.
- High therapeutic doses of mefloquine can cause neuropsychiatric reactions, and hence should be avoided in patients with epilepsy or psychiatric disorders.
- Artemisinin derivatives (eg, artesunate) are the most effective drugs for treating falciparum malaria, but are not commercially available in the United States.

⁹⁹CHAPTER 98 Antiprotozoal Drugs II: Miscellaneous Agents

Because of increasing world travel by Americans, and because of increased immigration by individuals from regions where infectious protozoa are endemic (South America, Asia, Africa), the incidence of protozoal infection in the United States is rising. The organisms encountered most frequently are *Entamoeba histolytica*, *Trichomonas vaginalis*, and *Giardia lamblia* (also known as *G. duodenalis*). Infections with most other protozoa (eg, *Leishmania* species, trypanosomes) are rare in North America. In approaching the antiprotozoal drugs, we begin by discussing the diseases that protozoa produce, after which we discuss the drugs used for treatment.

^{99.1}PROTOZOAL INFECTIONS

Our goal in this section is to describe the major protozoal infections—except for malaria, which is the subject of [Chapter 97](#). Discussion focuses on causative organisms, sites of infection, symptoms of disease, and preferred drug therapy. Causative organisms and drugs of choice are summarized in [Table 98-1](#).

^{99.1.1} Amebiasis

Amebiasis is an infestation with *Entamoeba histolytica*. In the United States, the disease affects between 1% and 4% of the population. Worldwide, amebiasis affects about 10% of the population, resulting in 100,000 deaths each year. The principal site of infestation is the intestine. However, amebas may migrate to other tissues, most commonly the liver, where abscesses may form. Amebiasis is usually asymptomatic. When symptoms *are* present, the most characteristic are diarrhea, abdominal pain, and weight loss.

Drugs of choice for amebiasis are *iodoquinol*, *paromomycin*, *metronidazole*, and *tinidazole*. Iodoquinol and paromomycin are active only against amebas residing in the intestine. Metronidazole and tinidazole are active against amebas that inhabit the intestine, the liver, and all other sites. For patients with asymptomatic intestinal infection, therapy with iodoquinol or paromomycin is sufficient. For patients with severe intestinal disease or with liver abscesses, metronidazole is given initially, followed by iodoquinol.

Iodoquinol, metronidazole, and tinidazole are discussed below. Paromomycin is discussed in [Chapter 86](#).

99.1.2 Cryptosporidiosis

Cryptosporidiosis is caused by *Cryptosporidium parvum*, a protozoan of the subclass Coccidia. *Cryptosporidium parvum* is an obligate intracellular parasite that can infect the intestinal tract of humans, cattle, and other mammals. Transmission is fecal-oral, often by ingesting water contaminated with livestock feces. The infection may also be acquired by animal-to-human contact, person-to-person contact, and ingestion of contaminated fruits or vegetables.

Cryptosporidiosis is characterized by diarrhea, abdominal cramps, anorexia, low-grade fever, nausea, and vomiting. For immunocompetent patients, the disease is generally mild and self-limited. However, for those who are severely immunosuppressed (owing to HIV infection, cancer chemotherapy, or other causes), the disease can be prolonged and life threatening, with diarrhea volume up to 20 L/day. Nitazoxanide [Alinia] is the treatment of choice. The drug is very effective in immunocompetent patients, and may also work in some who are immunosuppressed.

99.1.3 Giardiasis

Giardiasis is an infection with *Giardia lamblia*, also known as *G. duodenalis*. In the United States, giardiasis has a prevalence of 1 in 14,000. Infestation usually occurs by contact with contaminated objects or by drinking contaminated water. The primary habitat of *G. lamblia* is the upper small intestine. Occasionally, organisms migrate to the bile ducts and gallbladder. As many as 50% of affected individuals remain symptom free. However, symptoms that are both unpleasant and uncomfortable can develop. These include profound malaise; heartburn; vomiting; colicky pain after eating; and malodorous belching, flatulence, and diarrhea. The pain associated with giardiasis may mimic that of gallstones, appendicitis, peptic ulcers, or hiatal hernia. Drugs of choice are *metronidazole*, *tinidazole*, and *nitazoxanide*.

99.1.4 Leishmaniasis

The term *leishmaniasis* refers to infestation by certain protozoal species belonging to the genus *Leishmania*. Worldwide, the incidence of leishmaniasis is estimated at 10 million. The disease is acquired through the bite of sand flies indigenous to tropical and subtropical regions. In the human host, the parasites take up residence inside cells of the reticuloendothelial system.

Leishmaniasis has three different forms: *cutaneous*, *mucocutaneous*, and *visceral*. The particular form is determined by the species of *Leishmania* involved. The forms of leishmaniasis vary greatly in severity, ranging from mild (cutaneous leishmaniasis) to potentially fatal (visceral leishmaniasis). In *cutaneous* leishmaniasis, a nodule forms at the site of inoculation; later, this nodule may evolve into an ulcer that is very slow to heal. *Mucocutaneous* leishmaniasis is

characterized by ulceration in the mucosa of the mouth, nose, and pharynx. Symptoms of *visceral* leishmaniasis include fever, hepatosplenomegaly, liver dysfunction, hypoalbuminemia, pancytopenia, lymphadenopathy, and hemorrhage. Left untreated, visceral disease is frequently fatal. For all forms of leishmaniasis, *sodium stibogluconate* (given IM or IV) is the traditional treatment of choice. *Amphotericin B* (given IV) is an effective alternative. *Miltefosine*, an oral agent, is highly curative against visceral leishmaniasis, and probably against cutaneous disease. The drug appears reasonably safe and, owing to oral administration, is more convenient than stibogluconate or amphotericin B, both of which are given parenterally. Unfortunately, miltefosine is not available in the United States.

1158

1159

TABLE 98-1 Drugs of Choice for Protozoal Infection

Disease	Causative Protozoan	Drugs of Choice
Amebiasis	<i>Entamoeba histolytica</i>	Iodoquinol, paromomycin, metronidazole, tinidazole
Cryptosporidiosis	<i>Cryptosporidium parvum</i>	Nitazoxanide*
Giardiasis	<i>Giardia lamblia</i>	Metronidazole, tinidazole, nitazoxanide
Leishmaniasis	<i>Leishmania</i> species	Sodium stibogluconate, amphotericin B, miltefosine†
Toxoplasmosis	<i>Toxoplasma gondii</i>	Pyrimethamine plus sulfadiazine
Trichomoniasis	<i>Trichomonas vaginalis</i>	Metronidazole, tinidazole
Trypanosomiasis		
American (Chagas' disease)	<i>Trypanosoma cruzi</i>	Nifurtimox, benznidazole†
West African (sleeping sickness)	<i>Trypanosoma brucei gambiense</i>	
Early (hemolymphatic) stage		Pentamidine
Late (CNS) stage		Melarsoprol, eflornithine
East African (sleeping sickness)	<i>Trypanosoma brucei rhodesiense</i>	
Early (hemolymphatic) stage		Suramin
Late (CNS) stage		Melarsoprol

* Clearly effective in immunocompetent patients, but of little or no benefit to patients with HIV/AIDS.

† Not available in the United States.

99.1.5 Toxoplasmosis

Toxoplasmosis is caused by infection with *Toxoplasma gondii*, a protozoan of the class Sporozoa. The parasite is harbored by many animals as well as by humans. Infection is acquired most commonly by eating undercooked meat. However, toxoplasmosis may also be congenital. Congenital infection can damage the brain, eyes, liver, and other organs. Extensive disease is usually fatal. In immunocompetent adults, infection is usually asymptomatic, although it may involve the retina. However, in immunocompromised hosts, such as those with AIDS, the disease may progress to encephalitis and death. The treatment of choice is *pyrimethamine plus sulfadiazine*.

99.1.6 Trichomoniasis

Trichomoniasis is caused by *Trichomonas vaginalis*, a flagellated protozoan. Trichomoniasis is a common disease, affecting about 200 million people worldwide. The usual site of infestation is the genitourinary tract. Parasites may also inhabit the rectum. In females, infection results in vaginitis. In males, infection causes urethritis. The disease is usually transmitted by direct sexual contact but can also be acquired by contact with contaminated objects (eg, dildos). *Metronidazole* is the traditional drug of choice. However, *tinidazole* is just as effective and somewhat better tolerated—but much more expensive.

99.1.7 Trypanosomiasis

There are two major forms of trypanosomiasis: American trypanosomiasis and African trypanosomiasis. Both forms are caused by protozoal species in the genus *Trypanosoma*.

99.1.7.1 American Trypanosomiasis (Chagas' Disease).

Chagas' disease is caused by infection with *Trypanosoma cruzi*, a flagellated protozoan. The disease is prevalent in South America and the Caribbean, where it affects some 10 million people. The parasites are harbored in the digestive tract of certain blood-sucking bugs, and are transmitted as follows: the bug bites a sleeping person (usually on the face) and also defecates; the parasites, which are contained in the bug's feces, are then forced into the bite wound by rubbing or scratching. An early sign of the disease is swelling and severe inflammation at the site of inoculation. Over time, parasites invade cardiac cells and neurons of the myenteric plexus. Destruction of these cells can cause cardiomyopathy, megaesophagus, and megacolon. Deaths have occurred, usually secondary to cardiac injury. In its early phase, Chagas' disease

can be treated with *nifurtimox* or *benznidazole*. Unfortunately, these drugs are less effective against chronic infection.

99.1.7.2 African Trypanosomiasis (Sleeping Sickness).

African trypanosomiasis, transmitted by the bite of the tsetse fly, is caused by two subspecies of *Trypanosoma brucei*: *T. brucei gambiense*, which causes West African sleeping sickness, and *T. brucei rhodesiense*, which causes East African sleeping sickness. Disease caused by either subspecies has similar symptoms. Early symptoms, which involve the hemolymphatic system, include fever, lymphadenopathy, hepatosplenomegaly, dyspnea, and tachycardia. Late symptoms, which result from involvement of the central nervous system (CNS), include mental dullness, incoordination, and apathy. As CNS involvement advances, sleep becomes continuous and death may eventually follow. During the early (hemolymphatic) phase of African trypanosomiasis, *pentamidine* and *suramin* are the drugs of choice. (Pentamidine is preferred for disease caused by *T. brucei gambiense*, and suramin is preferred for disease caused by *T. brucei rhodesiense*.) During the late (CNS) stage, *melarsoprol* and *eflornithine* are drugs of choice. (Either drug can be used against *T. brucei gambiense*, but only melarsoprol is preferred for *T. brucei rhodesiense*.) All four drugs—pentamidine, suramin, eflornithine, and melarsoprol—can produce serious side effects. Treatment is difficult and frequently unsuccessful.

99.2 DRUGS OF CHOICE FOR PROTOZOAL INFECTIONS

99.2.1 Iodoquinol

Iodoquinol [Yodoxin] is a drug of choice for asymptomatic intestinal amebiasis. In addition, the drug is employed in conjunction with metronidazole to treat symptomatic intestinal infection and systemic amebiasis. In these last two cases, iodoquinol is administered after treatment with metronidazole to eliminate any surviving intestinal parasites. Very little iodoquinol is absorbed, and hence the drug is not active against systemic amebiasis.

Iodoquinol is generally well tolerated. Mild reactions occur occasionally. These include rash, acne, slight thyroid enlargement, and GI effects (nausea, vomiting, diarrhea, cramps, pruritus ani). Rarely, prolonged therapy at very high doses has caused optic atrophy with permanent loss of vision.

Iodoquinol [Yodoxin] is available in tablets (210 and 650 mg) and as a powder for oral administration, preferably after a meal. The usual adult dosage is 650 mg 3 times a day for 20 days. The dosage for children is 30 to 40 mg/kg/day (given in three divided doses) for 20 days.

1159

1160

99.2.2 Metronidazole

Metronidazole [Flagyl, Protostat, Metric 21], a drug in the nitroimidazole family, is active against several protozoal species, including *E. histolytica*, *G. lamblia*, and *Trichomonas vaginalis*. The drug is also active against anaerobic bacteria (see [Chapter 90](#)).

99.2.2.1 Therapeutic Uses.

Metronidazole is a drug of choice for *symptomatic intestinal amebiasis* and *systemic amebiasis*. Because most of each dose is absorbed in the small intestine, metronidazole concentrations in the colon remain low, allowing amebas there to survive. To kill these survivors, metronidazole is followed by iodoquinol, an amebicidal drug that achieves high concentrations in the colon.

Metronidazole is a drug of choice for *giardiasis*, and for *trichomoniasis* in males as well as females.

Many anaerobic bacteria are sensitive to metronidazole. Antibacterial applications are discussed in [Chapter 90](#).

99.2.2.2 Mechanism of Action.

Metronidazole is a prodrug that remains harmless until converted to a more chemically reactive form, a process that takes place only within anaerobic cells. Because mammalian cells are aerobic, they cannot activate the drug and hence are largely spared. How does activated metronidazole work? It interacts with DNA, causing strand breakage and loss of helical structure. The resulting impairment of DNA function is thought responsible for the drug's antimicrobial and mutagenic actions.

99.2.2.3 Pharmacokinetics.

Metronidazole may be given PO or IV. Blood levels are similar with both routes. Following oral administration, metronidazole is rapidly absorbed and undergoes widespread distribution. The drug crosses membranes with ease, including those of the placenta and the blood-brain barrier. As a result, drug levels in cerebrospinal fluid, saliva, and breast milk equal those in plasma. Extensive metabolism occurs in the liver. Metabolites and unchanged drug are excreted in the urine. The half-life is 8 hours.

99.2.2.4 Adverse Effects.

Metronidazole produces a variety of untoward effects, but these rarely lead to termination of treatment. The most common side effects are nausea, headache, dry mouth, and an unpleasant metallic taste. Other common effects include stomatitis, vomiting, diarrhea, insomnia, vertigo, and weakness. Harmless darkening of the urine may occur, and patients should be forewarned. Certain neurologic effects (numbness in the extremities, ataxia, convulsions) occur rarely. If these develop, metronidazole should be withdrawn. Metronidazole should not be used by patients with active disease of the CNS. Carcinogenic effects have been observed in rodents, but there is no evidence of cancer in humans.

99.2.2.5 Use in Pregnancy and Lactation.

Metronidazole readily crosses the placenta, and is mutagenic in bacteria. However, experience to date has not shown fetal harm in humans. Nonetheless, it is recommended that metronidazole be avoided during the first trimester, and employed with caution throughout the rest of pregnancy.

Metronidazole can be detected in breast milk up to 72 hours after administration. Mothers should interrupt breast-feeding until 3 days after the last dose.

99.2.2.6 Drug Interactions.

99.2.2.6.1 Alcohol and Disulfiram.

Metronidazole has disulfiram-like actions, and hence can produce unpleasant or dangerous effects if used in conjunction with alcohol. Accordingly, patients must be warned against consuming alcoholic beverages or any product that contains alcohol. The combination of metronidazole with disulfiram itself can cause a psychotic reaction, and hence must be avoided.

99.2.2.6.2 Warfarin.

Metronidazole inhibits the inactivation of warfarin, an anticoagulant. Dosage of warfarin may need to be reduced during metronidazole therapy and for 8 days after.

99.2.2.6.3 Phenytoin, Lithium, Fluorouracil, Cyclosporine, and Tacrolimus.

Metronidazole can increase levels of these drugs. Patients should be monitored for signs of toxicity.

99.2.2.6.4 Cholestyramine.

Cholestyramine can bind with metronidazole in the GI tract, and thereby reduce metronidazole absorption by 20%. Dosing with these drugs should be separated.

99.2.2.6.5 Drugs That Affect CYP3A4.

Because metronidazole is a substrate for CYP3A4 (the 3A4 isozyme of cytochrome P450), agents that induce the enzyme (eg, phenobarbital, rifampin, phenytoin) can reduce levels of metronidazole, and agents that inhibit the enzyme (eg, ketoconazole) can increase levels of metronidazole.

99.2.2.7 Preparations, Dosage, and Administration.

Metronidazole [Flag-yl, Protostat, Metric 21] is available in capsules (375 mg), standard tablets (250 and 500 mg), and extended-release tablets (750 mg); in solution for injection (5 mg/mL); and as a powder to be reconstituted for injection. For protozoal infections, the oral formulations are used. Antibacterial therapy usually requires IV treatment. Dosages for bacterial infections are presented in [Chapter 90](#). Dosages for protozoal infections are as follows:

- *Amebiasis*—*adults*, 500 to 750 mg 3 times a day for 7 to 10 days; *children*, 35 to 50 mg/kg/day in three divided doses for 7 to 10 days. Following treatment with metronidazole, iodoquinol is given for 20 days.
- *Trichomoniasis*—*adults*, either 2 gm just once *or* 500 mg twice a day for 7 days; *children*, 5 mg/kg 3 times a day for 7 days.
- *Giardiasis*—*adults*, 250 mg 3 times a day for 5 days; *children*, 5 mg/kg 3 times a day for 5 days.

99.2.3 Tinidazole

Tinidazole [Tindamax] is an antiprotozoal drug similar to metronidazole. Both agents are nitroimidazoles, and both have similar actions, indications, interactions, and adverse effects.

Pharmacology for Nursing Care, 7th Edition

Tinidazole has a longer half-life than metronidazole, and hence dosing is more convenient (it's done less often and on fewer days). However, metronidazole is much less expensive. Tinidazole was approved by the Food and Drug Administration (FDA) in 2004, but has been available in other countries for over 25 years.

99.2.3.1 Therapeutic Uses.

Tinidazole is indicated for trichomoniasis in adults, and for giardiasis, intestinal amebiasis, and amebic liver abscesses in adults and children over 3 years of age. Like metronidazole, tinidazole is considered a drug of choice for all of these infections.

99.2.3.2 Mechanism of Action.

Tinidazole has the same mechanism as metronidazole. Both drugs enter anaerobic cells, undergo conversion to a more reactive form, and then interact with DNA to cause strand breakage and loss of helical structure.

99.2.3.3 Pharmacokinetics.

Tinidazole is administered by mouth, and absorption is rapid and complete. Food decreases the rate of absorption but not the extent. Tinidazole crosses membranes with ease, and hence is distributed to virtually all tissues and body fluids. The drug crosses the blood-brain barrier and the placental barrier, and also enters breast milk. Tinidazole is metabolized in the liver by CYP3A4. Excretion is via the bile and urine. Tinidazole has a half-life of 12 to 14 hours, nearly twice that of metronidazole.

99.2.3.4 Adverse Effects.

Adverse effects are like those of metronidazole, although tinidazole is better tolerated. Gastrointestinal effects—metallic taste, stomatitis, anorexia, dyspepsia, nausea, vomiting—are most common. Like metronidazole, tinidazole carries a small risk of seizures and peripheral neuropathy. If abnormal neurologic signs develop, tinidazole should be immediately withdrawn. In patients with existing CNS disease, tinidazole should be used with caution.

99.2.3.5 Use in Pregnancy and Lactation.

Tinidazole is in FDA Pregnancy Risk Category C: Animal studies show a risk of fetal harm, but no controlled studies have been done in women. Like metronidazole, tinidazole should not be used during the first trimester of pregnancy.

Tinidazole can be detected in breast milk up to 72 hours after administration. Mothers should not breast-feed while taking the drug and for 3 days after.

99.2.3.6 Drug Interactions.

No studies on the interactions of tinidazole with other drugs have been conducted. However, because tinidazole and metronidazole have similar structures and because both are metabolized by CYP3A4, the interactions that occur with metronidazole are likely to occur with tinidazole. Accordingly, tinidazole is likely to potentiate the effects of warfarin, lithium, fluorouracil, cyclosporine, tacrolimus, and injectable phenytoin. Cholestyramine may decrease the absorption of tinidazole, and oxytetracycline may antagonize the effects of tinidazole. Because tinidazole is a substrate for CYP3A4, inducers of the enzyme may reduce the effects of tinidazole, and inhibitors may increase the effects of tinidazole. Like metronidazole, tinidazole has disulfiram-like actions, and hence patients should not consume disulfiram itself, alcoholic beverages, or any product that contains alcohol.

99.2.3.7 Preparations, Dosage, and Administration.

Tinidazole [Tindamax] is available in 250- and 500-mg tablets. For patients unable to swallow tablets whole, the tablets may be crushed and mixed with cherry syrup. To minimize GI distress, tinidazole should be taken with food. Dosages are as follows:

1160

1161

- *Trichomoniasis or giardiasis*—adults, 2 gm once; children, 50 mg/kg (maximum 2 gm) once
- *Intestinal amebiasis*—adults, 2 gm once daily for 3 days; children, 50 mg/kg (maximum 2 gm) once daily for 3 days
- *Amebic liver abscess*—adults, 2 gm once daily for 5 days; children, 50 mg/kg (maximum 2 gm) once daily for 5 days

99.2.4 Benznidazole

Benznidazole [Rochagan, in Brazil], a relative of metronidazole and tinidazole, is a drug of choice for American trypanosomiasis (Chagas' disease). The adult dosage is 2.5 to 3.5 mg/kg twice daily, and the pediatric dosage is 5 mg/kg twice daily. For adults and children, the duration of treatment is 30 to 90 days. At this time, benznidazole is not available in the United States.

99.2.5 Nitazoxanide

99.2.5.1 Therapeutic Uses.

Nitazoxanide [Alinia] is approved for diarrhea caused by *C. parvum* (in children only) and by *G. lamblia* (in children and adults). Although we have other effective drugs for giardiasis (eg, metronidazole, tinidazole), nitazoxanide is our first effective drug for cryptosporidiosis.

Unfortunately, when used for *C. parvum* infections, nitazoxanide is only effective in children who are immunocompetent; among children who are immunosuppressed, the drug is no more effective than placebo. Results in immunocompromised adults may be more favorable: When given to adults with cryptosporidiosis and AIDS, a dosage of 1000 mg twice a day for 14 days cured 67% of patients, compared with 25% of those receiving placebo.

99.2.5.2 Actions.

Nitazoxanide appears to work by disrupting protozoal energy metabolism. Specifically, the drug blocks electron transfer mediated by pyruvate:ferredoxin oxidoreductase, and thereby inhibits anaerobic energy metabolism. In addition to its activity against *C. parvum* and *G. lamblia*, nitazoxanide is active against other enteric protozoa (*Isospora belli* and *Entamoeba histolytica*) as well as some helminths, including *Ascaris lumbricoides*, *Ancylostoma duodenale*, *Trichuris trichiura*, *Taenia saginata*, and *Fasciola hepatica*.

99.2.5.3 Pharmacokinetics.

Nitazoxanide is well absorbed following oral administration. In the blood, the drug undergoes rapid conversion to its active metabolite, tizoxanide, which then undergoes nearly complete (more than 99.9%) binding to plasma proteins. Tizoxanide levels peak between 1 and 4 hours after nitazoxanide administration, and then decline owing to excretion in the urine, bile, and feces.

99.2.5.4 Adverse Effects.

Nitazoxanide is generally well tolerated. In clinical trials, the most common adverse effects were abdominal pain, diarrhea, vomiting, and headache. However, these effects were just as common in subjects taking placebo. In some patients, the drug caused yellow discoloration of the sclerae (whites of the eyes), which resolved following drug withdrawal. Nitazoxanide is in FDA Pregnancy Risk Category B: Animal studies show no evidence of impaired fertility or fetal harm.

99.2.5.5 Drug Interactions.

Because nitazoxanide is highly protein bound, it might interact with other agents that are highly bound. Specifically, nitazoxanide might displace other drugs from their binding sites, thereby increasing their effects and, conversely, other highly bound agents could displace nitazoxanide, thereby increasing its effects.

99.2.5.6 Preparations, Dosage, and Administration.

99.2.5.6.1 Oral Suspension.

Nitazoxanide oral suspension [Alinia] is indicated for diarrhea caused by *G. lamblia* or *C. parvum* in children ages 1 through 11 years, and for diarrhea caused by *G. lamblia* (but not *C. parvum*) in adults. Nitazoxanide is supplied as a pink powder that, when mixed with 48 mL of water, forms a strawberry-flavored, 20-mg/mL suspension. Administration is done with food. The suspension may be stored at room temperature for 7 days, after which it should be discarded. Dosage depends on age as follows:

- For children ages 12 to 48 months, give 100 mg (5 mL) every 12 hours for 3 days.
- For children ages 4 to 11 years, give 200 mg (10 mL) every 12 hours for 3 days.
- For patients 12 years and older, give 500 mg (25 mL) every 12 hours for 3 days.

99.2.5.6.2 Tablets.

Nitazoxanide tablets [Alinia] are indicated only for diarrhea caused by *G. lamblia*, and only for patients at least 12 years old. The dosage is 1 tablet (500 mg) every 12 hours for 3 days. Administration is done with food.

99.2.6 Pentamidine

99.2.6.1 Target Diseases and Actions.

Pentamidine [Pentam 300, Pentacarinat, NebuPent] is highly effective against West African sleeping sickness, a disease is caused by *T. brucei gambiense*, and against pneumocystis pneumonia (PCP), a disease caused by a fungus named *Pneumocystis jiroveci* (formerly thought to be *Pneumocystis carinii*). The drug has multiple actions, including disrupting the synthesis of DNA, RNA, phospholipids, and proteins. However, we don't know which of these actions is responsible for antiprotozoal effects.

99.2.6.2 Uses.

99.2.6.2.1 Pneumocystis Pneumonia.

For therapy of PCP, pentamidine is given parenterally and by inhalation. Parenteral therapy is used to treat active PCP. In contrast, inhalational therapy is used to *prevent* PCP in high-risk HIV-positive patients, defined as patients with (1) a history of one or more episodes of PCP or (2) peripheral CD4 lymphocyte counts below 200 cells/mm³.

99.2.6.2.2 West African Sleeping Sickness.

Pentamidine is given by IM injection to treat sleeping sickness. However, the drug is not approved by the FDA for this disorder.

99.2.6.3 Pharmacokinetics.

For treatment of active PCP, pentamidine is administered IM or IV. Equivalent blood levels are achieved with both routes. The drug is extensively bound in tissues. Penetration to the brain and cerebrospinal fluid is poor. Between 50% and 65% of each dose is excreted rapidly in the urine. The remaining drug is excreted slowly, over a month or more.

99.2.6.4 Adverse Effects Associated with Parenteral Pentamidine.

Pen-tamidine can produce serious side effects when given IM or IV. Caution is needed.

Sudden and severe *hypotension* occurs in about 1% of patients. The fall in blood pressure may cause tachycardia, dizziness, and fainting. To minimize hypotensive responses, patients should receive the drug while lying down. Blood pressure should be monitored closely.

Hypoglycemia and *hyperglycemia* have occurred. Hypoglycemia has been associated with necrosis of pancreatic islet cells and excessive insulin levels. The cause of hyperglycemia is unknown. Because of possible fluctuations in glucose levels, blood glucose should be monitored daily.

Intramuscular administration is painful. Necrosis at the injection site followed by formation of a sterile abscess is common.

Some adverse effects can be life threatening when severe. These reactions and their incidences are leukopenia (2.8%), thrombocytopenia (1.7%), acute renal failure (0.5%), hypocalcemia (0.2%), and dysrhythmias (0.2%).

99.2.6.5 Adverse Effects Associated with Aerosolized Pentamidine.

Inhaled pentamidine does not cause the severe effects associated with parenteral pentamidine. The most common reactions are cough (38%) and bronchospasm (15%). Both reactions are more pronounced in patients with asthma or a history of smoking. Fortunately, these reactions can be controlled with an inhaled bronchodilator. They rarely necessitate pentamidine withdrawal.

99.2.6.6 Preparations, Dosage, and Administration.

99.2.6.6.1 Pneumocystis Pneu-monia.

Pentamidine isethionate *for injection* [Pentam 300, Pentacarinat] is supplied in 300-mg, single-dose vials. For treatment of active PCP, the dosage for adults and children is 3 to 4 mg/kg IV daily for 2 to 3 weeks. Administration must be done slowly (over 60 minutes).

Pentamidine isethionate *aerosol* [NebuPent] is used for prophylaxis of PCP in patients with AIDS. The dosage is 300 mg once every 4 weeks. Administration is performed with a Respirgard II nebulizer by Marquest. Solutions should be freshly prepared.

99.2.6.6.2 West African Sleeping Sickness.

Administration is by IM injection. The dosage for adults and children is 4 mg/kg/day for 7 days.

99.2.7 Suramin

99.2.7.1 Actions and Uses.

Suramin sodium [Germanin] is a drug of choice for the early phase of East African trypanosomiasis (sleeping sickness); for the late phase of the disease (ie, the stage of CNS involvement), melarsoprol and eflornithine are preferred. Suramin is known to inhibit many trypanosomal enzymes; however, its primary mechanism of action has not been established.

99.2.7.2 Pharmacokinetics.

The drug is poorly absorbed from the GI tract, and hence must be given parenterally (IV). Suramin binds tightly to plasma proteins and remains in the bloodstream for months. Penetration into cells is low. Excretion is renal.

1161

99.2.7.3 Adverse Effects.

Side effects can be severe, and hence treatment should take place in a hospital. Frequent reactions include vomiting, itching, rash, paresthesias, photophobia, and hyperesthesia of the palms and soles. Suramin concentrates in the kidneys and can cause local damage, resulting in the appearance of protein, blood cells, and casts in the urine. If urinary casts are observed, treatment should cease. Rarely, a shock-like syndrome develops after IV administration. To minimize the risk of this reaction, a small test dose (100 to 200 mg) is administered; in the absence of a severe reaction, full doses may follow.

99.2.7.4 Preparations, Dosage, and Administration.

Suramin sodium [Germanin] is available from the CDC Drug Service. The drug is supplied in 1-gm ampules. Administration is by slow IV infusion. Suramin is unstable, and hence fresh solutions must be made daily. The adult dosage is 1 gm IV on days 1, 3, 7, 14, and 21. The pediatric dosage is 20 mg/kg IV on days 1, 3, 7, 14, and 21. Possible revisions in these dosage recommendations should be obtained from the CDC.

99.2.8 Melarsoprol**99.2.8.1 Therapeutic Use.**

Melarsoprol [Arsobal, Mel-B] is a drug of choice for both East African and West African trypanosomiasis (sleeping sickness). The drug is employed during the *late* stage of the disease (ie, after CNS involvement has developed). For earlier stages, suramin and pentamidine are preferred.

99.2.8.2 Mechanism of Action.

Melarsoprol is an organic arsenical compound that reacts with sulfhydryl groups of proteins. Antiparasitic effects result from inactivation of enzymes. This same action appears to underlie the serious toxicity of the drug. Melarsoprol is more toxic to parasites than to humans because it penetrates parasitic membranes more easily than human cells.

99.2.8.3 Adverse Effects.

Melarsoprol is quite toxic, and hence adverse reactions are common. Frequent effects include hypertension, albuminuria, peripheral neuropathy, myocardial damage, and Herxheimer-type

reactions. Reactive encephalopathy develops in 10% of patients, and carries a 15% to 40% risk of death.

99.2.8.4 Preparations, Dosage, and Administration.

Melarsoprol [Arsobal, Mel-B] is administered by slow IV injection. The drug is highly irritating to tissues, and hence avoiding extravasation is important. Because of its toxicity, melarsoprol should be administered in a hospital setting. Melarsoprol can be obtained through the CDC Drug Service. The drug is not available commercially.

99.2.8.4.1 East African Trypanosomiasis.

Treatment for adults and children consists of an initial course (2 to 3.6 mg/kg IV daily for 3 days) followed in 7 days by a second course (3.6 mg/kg IV daily for 3 days), followed in 7 days by a third course (3.6 mg/kg IV daily for 3 days).

99.2.8.4.2 West African Trypanosomiasis.

The dosage for adults and children is 2.2 mg/kg/day for 10 days.

99.2.9 Eflornithine

99.2.9.1 Actions and Uses.

Eflornithine [Ornidyl] is indicated for patients with late-stage African trypanosomiasis (sleeping sickness). The drug is highly effective against *T. gambiense* (West African sleeping sickness), but only variably active against *T. rhodesiense* (East African sleeping sickness). In both cases, benefits derive from irreversible inhibition of ornithine decarboxylase, an enzyme needed for biosynthesis of polyamines, which are required by all cells for division and differentiation. Parasites weakened by eflornithine become highly vulnerable to lethal attack by host defenses. Because cells of the host can readily synthesize more ornithine decarboxylase to replace inhibited enzyme, cells of the host are spared.

As discussed in [Chapter 104](#), eflornithine is also available in a topical formulation, marketed as Vaniqa, for use by women to remove unwanted facial hair.

99.2.9.2 Pharmacokinetics.

Eflornithine is given IV. Once in the blood, the drug is well distributed to body fluids and tissues, including the CNS. Eflornithine has a half-life of 100 minutes and is eliminated largely unchanged in the urine.

99.2.9.3 Adverse Effects.

The most common adverse effects are anemia (48%), diarrhea (39%), and leukopenia (27%). Seizures may occur early in therapy but then subside, despite continued treatment. Because IV administration of eflornithine requires large volumes of fluid, fluid overload may develop over the course of treatment. Eflornithine can also cause hair loss. In fact, the drug is now available for topical use to remove facial hair (see [Chapter 104](#)).

99.2.9.4 Preparations, Dosage, and Administration.

Eflornithine is supplied as a concentrated solution (200 mg/mL in 100-mL vials) and must be diluted for IV infusion. To treat West African sleeping sickness in adults and children, the dosage is 100 mg/kg IV 4 times a day for 14 days. Eflornithine is available only from the CDC Drug Service.

99.2.10 Nifurtimox

99.2.10.1 Therapeutic Use.

Nifurtimox [Lampit] is a drug of choice for American trypanosomiasis (Chagas' disease). The drug is most effective in the acute stage of the disease, curing about 80% of patients. Chronic disease is less responsive.

99.2.10.2 Pharmacokinetics.

Nifurtimox is well absorbed from the GI tract and undergoes rapid and extensive metabolism. Metabolites are excreted in the urine.

99.2.10.3 Adverse Effects.

Therapy is prolonged, and significant untoward effects occur often. Gastrointestinal effects (anorexia, nausea, vomiting, abdominal pain) and peripheral neuropathy are especially common. Weight loss resulting from GI disturbance may require treatment to stop. Additional

common reactions include rash and CNS effects (memory loss, insomnia, vertigo, headache). In people with a deficiency of glucose-6-phosphate dehydrogenase, nifurtimox can cause hemolysis.

99.2.10.4 Preparations, Dosage, and Administration.

Nifurtimox [Lampit] is supplied in 100-mg tablets. In the United States, the drug is available only from the CDC Drug Service. The adult dosage is 8 to 10 mg/kg/day (in three or four doses) for 90 to 120 days. For young children (ages 1 through 10 years), the dosage is 15 to 20 mg/kg/day (in four doses) for 90 to 120 days. For older children (ages 11 to 16 years), the dosage is 12.5 to 15 mg/kg/day (in four doses) for 90 to 120 days.

99.2.11 Pyrimethamine

Pyrimethamine [Daraprim], combined with sulfadiazine, is the treatment of choice for toxoplasmosis. Pyrimethamine (combined with sulfadoxine) is also used to treat malaria (see [Chapter 97](#)). For toxoplasmosis, the adult dosage is 25 to 100 mg PO daily for 3 to 4 weeks. The pediatric dosage is 2 mg/kg PO daily for 2 days, followed by 1 mg/kg PO daily for 4 weeks. For adults and children, each dose of pyrimethamine should be accompanied by 10 mg of folinic acid (to reduce side effects). In addition, the regimen must include sulfadiazine: for adults, 1 to 1.5 gm 4 times a day for 3 to 4 weeks; for children, 100 to 200 mg/kg/day for 3 to 4 weeks. The basic pharmacology of pyrimethamine is discussed in [Chapter 97](#).

99.2.12 Sodium Stibogluconate

Sodium stibogluconate [Pentostam] is a drug of choice for leishmaniasis. The mechanism of action is unknown. The drug is poorly absorbed from the GI tract, and hence must be given parenterally (IM or IV). Sodium stibogluconate undergoes little metabolism and is excreted rapidly in the urine. Although severe side effects can occur, the drug is generally well tolerated. The most frequent adverse reactions are muscle pain, joint stiffness, and bradycardia. Changes in the electrocardiogram are common and occasionally precede serious dysrhythmias. Liver and renal dysfunction, shock, and sudden death occur rarely. Sodium stibogluconate is supplied in aqueous solution for IM and IV injection. For leishmaniasis, the usual adult and pediatric dosage is 20 mg/kg/day (IM or IV) for 20 to 28 days. In the United States, the drug is available only from the CDC Drug Service.

99.2.13 Miltefosine

Miltefosine [Impavido] is the first *oral* agent for *leishmaniasis*. The drug was originally developed to treat cancer. Antiprotozoal activity wasn't revealed until miltefosine was tested in cancer patients who also had leishmaniasis. The mechanism underlying benefits in leishmaniasis is unclear. Studies conducted in India indicate that oral miltefosine is both safe and effective for treating *visceral* leishmaniasis. Preliminary studies indicate the drug is also highly effective against *cutaneous* disease. Because miltefosine is taken by mouth, rather than by injection, the drug is much more convenient than the alternatives, namely, sodium stibogluconate (administered IM or IV) and amphotericin B (administered IV).

Miltefosine is better tolerated than either sodium stibogluconate or amphotericin B. The most common reactions are vomiting (38%) and diarrhea (20%). Mild hepatotoxicity is seen in some patients, but it resolves during the second week of treatment. Reversible renal damage may also occur. Miltefosine causes fetal abnormalities in laboratory animals, and hence must not be used during pregnancy. Effective contraception is required while taking the drug and for 2 months after.

The recommended dosage for adults and children is 2.5 mg/kg/day for 28 days. At this time, miltefosine is not available in the United States.

1162

99.2.13.1

KEY POINTS

- The principal protozoal infections seen in the United States are trichomoniasis, giardiasis, and amebiasis.
- Metronidazole is a drug of choice for trichomoniasis, giardiasis, and symptomatic or systemic amebiasis.
- Iodoquinol is the drug of choice for asymptomatic amebiasis.
- Patients taking metronidazole should be warned against consuming alcohol because of the risk of a disulfiram-like reaction.

1163

¹⁰⁰CHAPTER 99 Ectoparasiticides

Ectoparasites are parasites that live on the surface of the host. Most ectoparasites that infest humans live on the skin and hair. Some live on clothing and bedding, moving to the host only to feed. The principal ectoparasites that infest humans are mites and lice. Infestation with mites is known as *scabies*. Infestation with lice is known as *pediculosis*. Both conditions are characterized by intense pruritus (itching). With the exception of ivermectin, all of the drugs used for treatment are topical.

^{10...}ECTOPARASITIC INFESTATIONS

^{100.1.1}Scabies (Infestation with Mites)

Scabies is caused by infestation with *Sarcoptes scabiei*, an organism known commonly as the itch mite. Irritation results from the female mite burrowing beneath the skin to lay eggs. Burrows may be visible as small ridges or dotted lines. In adults, the most common sites of infestation are the wrists, elbows, nipples, navel, genital region, and webs of the fingers. In children, infestation is most likely on the head, neck, and buttocks.

The primary symptom of scabies is pruritus. Itching is most intense just after going to bed. Scratching may result in abrasion and secondary infection.

Transmission of scabies is usually by direct contact, either sexual or of a less intimate nature. Scabies may also be transmitted through contact with infested linen, towels, or clothing.

Scabies is usually treated with a pesticide-containing lotion or cream. To eradicate mites, the entire body surface must be treated (excluding the face and scalp in adults). To prevent reinfestation, bedding and intimate clothing should be machine washed and dried.

Several drugs can kill mites. *Permethrin* (5% cream formulation) is the drug of choice. This preparation is effective in just one application. *Crotamiton* is a preferred alternative. In addition, there is evidence that a single oral dose (200 mcg/kg) of *ivermectin* [Stromectol] can cure scabies, although the drug is not approved for this use.

^{100.1.2}Pediculosis (Infestation with Lice)

Pediculosis is a general term referring to infestation with any of several kinds of lice. The types of lice encountered most frequently are *Pediculus humanus capitis* (head louse), *Pediculus humanus corporis* (body louse), and *Phthirus pubis* (pubic or crab louse). Infestation with any of these insects causes pruritus. Infestations with head, pubic, and body lice differ with regard to mode of acquisition and method of treatment.

100.1.2.1 Pubic Lice

Pubic lice, commonly known as *crabs* (because pubic lice are shaped like crabs), usually reside on the skin and hair of the pubic region. However, pubic lice may also be found on the eyelashes and other places. As a rule, infestation is transmitted through sexual contact. Consequently, crabs are most common among people who have multiple sexual partners. Two preparations—*permethrin* (1% lotion) and *malathion* (0.5% lotion)—are drugs of choice for eliminating crabs. Alternatives include *pyrethrins with piperonyl butoxide* (gel, lotion, shampoo) and oral *ivermectin* (200 mcg/kg once). Infestation of the eyelashes is treated with petrolatum ophthalmic ointment. Clothing and linen should be disinfected by washing in very hot water, followed by machine drying at high temperature.

100.1.2.2 Head Lice

Head lice reside on the scalp and lay their nits (eggs) on the hair. Adult lice may be difficult to observe. Nits, however, are usually visible. Infestation may be associated with hives, boils, impetigo, and other skin disorders. The head louse is more democratic than the pubic or body louse and can be found infesting people from all socioeconomic groups. Head lice may be transmitted by close personal contact and (perhaps) by contact with infested clothing, hairbrushes, furniture, and other objects. Because humans are the only host for these obligate parasites, infestation cannot be acquired through contact with pets or any other animals.

Treatments of choice are *permethrin* and *malathion*. Both drugs kill adult lice as well as nits. A few days after drug treatment, dead lice (and remaining live lice) should be removed from the hair with a fine-toothed comb. Eradication of head lice does not require shaving or cutting the hair. Combing with a fine-toothed comb may be as effective as malathion or permethrin.

100.1.2.3 Body Lice

Despite their name, body lice reside not on the body but on clothing. These lice move to the body only to feed. Consequently, body lice are rarely seen on the skin. Rather, they can be found in bed linens and the seams of garments. Transmission of body lice is by contact with infested clothing or bedding. Body lice are relatively uncommon in the United States, where regular laundering precludes infestation. Infestation is most likely among vagrants and other people whose clothes may not be frequently washed. The majority of body lice can be removed from the host simply by removing his or her clothing. Those lice that remain on the body can be killed by applying a pesticide; *permethrin* and *malathion* are drugs of choice. Clothing and bedding should be disinfected by washing and drying at high temperature. Recent data indicate that giving three weekly doses of oral *ivermectin* is an effective way to eradicate body lice.

1164

1165

^{10...} PHARMACOLOGY OF ECTOPARASITICIDES

As a rule, ectoparasitic infestations are treated with *topical drugs*. These agents are available in the form of creams, gels, lotions, liquids, and shampoos. Only one ectoparasiticide—ivermectin—is administered orally. Properties of the major ectoparasiticides are summarized in [Table 99-1](#).

^{100.2.1} Permethrin

^{100.2.1.1} Basic Pharmacology

^{100.2.1.1.1} Actions and Uses.

Permethrin [Nix, Elimite, Acticin] is toxic to mites, lice, and their ova. Residual activity persists for 2 or more weeks after treatment. The drug kills adult insects by disrupting nerve traffic, thereby causing paralysis. In addition to killing mites and lice, permethrin is active against fleas and ticks. The 1% formulation [Nix] is a drug of choice for lice. The 5% formulation [Elimite, Acticin] is the drug of choice for scabies. As a rule, only one application is required.

^{100.2.1.1.2} Resistance.

Permethrin fails to eradicate *head lice* in about 5% of patients. Drug resistance is suspected, although proof is lacking. To manage treatment-resistant head lice, some clinicians recommend prolonged treatment (several hours rather than the usual 10 minutes) or use of the 5% formulation [Elimite, Acticin] rather than the 1% formulation [Nix]. It should be noted, however, that these practices are controversial.

^{100.2.1.1.3} Pharmacokinetics.

Very little (about 2%) of topical permethrin is absorbed. The fraction absorbed is rapidly inactivated and excreted in the urine.

^{100.2.1.1.4} Adverse Effects.

Topical permethrin is devoid of serious adverse effects. The drug may cause some exacerbation of the itching, erythema, and edema normally associated with pediculosis. Other reactions include temporary sensations of burning, stinging, and numbness.

100.2.1.2 Preparations and Administration

100.2.1.2.1 Preparations.

Permethrin is formulated in two concentrations: (1) a 1% liquid [Nix] used for lice and (2) a 5% cream [Elimite, Acticin] used for scabies.

100.2.1.2.2 Administration.

100.2.1.2.2.1 Head Lice.

Before applying permethrin (1% liquid) to remove head lice, the hair should be washed, rinsed, and towel dried. Permethrin is then applied in an amount sufficient to saturate the hair and scalp. After 10 minutes, permethrin should be removed with a warm-water rinse. Nits should be removed with a fine-toothed comb. If needed, re-treatment can be done in 7 days. However, because antiparasitic activity persists, re-application is required in less than 5% of cases.

100.2.1.2.2.2 Scabies.

The 5% cream [Elimite, Acticin] is massaged into the skin, from the head to the soles of the feet. After 8 to 14 hours, the cream is removed by washing. Thirty grams is sufficient for the average adult. Only one application is needed.

100.2.2 Malathion

100.2.2.1 Actions and Uses.

Malathion [Ovide] is an organophosphate cholinesterase inhibitor (see [Chapter 15](#)). The drug kills lice and their ova. Humans and other mammals are not harmed because an enzyme in their blood converts malathion to nontoxic metabolites. The drug is approved for treatment of head lice. It is also used widely as an insecticide.

100.2.2.2 Adverse Effects and Interactions.

The preparation used topically for head lice is devoid of significant adverse effects. Scalp irritation occurs occasionally. No systemic toxicity has been reported. Likewise, no drug interactions have been reported. Malathion lotion contains a high concentration of alcohol, and hence presents a risk of fire. Also, the drug smells bad.

TABLE 99-1 Preferred Drugs for Mites and Lice

		Indications			
Generic Name	Trade Name	Scabies (Mites)	Pediculosis (Lice)	Dosage Forms	Adverse Effects
Topical Medications					
Permethrin	Nix	✓		Liquid: 1%	Occasional; burning, stinging, itching, numbness, pain, rash, erythema, edema
	Elimite, Acticin		✓	Cream: 5%	
Crotamiton	Eurax	✓		Cream: 10%	Occasional: rash, conjunctivitis
				Lotion: 10%	
Malathion	Ovide		✓	Lotion: 0.5%	Occasional: local irritation
Pyrethrins plus piperonyl butoxide	RID, others		✓	Gel	Occasional: irritation to eyes and mucous membranes following inadvertent contact
				Lotion	
				Mousse	
				Shampoo	
Systemic Medication					
Ivermectin	Stromectol	*	*	Tablet: 3 mg, 6 mg	Rare: hypertension

* Although ivermectin is effective against mites and lice, the drug is not approved by the Food and Drug Administration for treating these infestations.

1165

100.2.2.3 Preparations and Administration.

1166

Malathion [Ovide] is available in a 0.5% lotion. The preparation is applied to dry hair, gently massaged until the scalp is moist, and allowed to dry naturally. (The lotion is flammable because of its 78% alcohol content. Hence, hair dryers and other sources of heat should be avoided until the alcohol has dried.) Package labeling recommends waiting 8 to 12 hours before washing malathion off with shampoo. However, recent data indicate that malathion is highly effective with only 20 minutes of exposure. Once the drug has been washed away, dead lice and ova can be removed with a fine-toothed comb. Treatment may be repeated in 7 to 9 days if needed.

100.2.3 Crotamiton

Crotamiton [Eurax] is used to treat scabies. The drug is not indicated for pediculosis. This agent has scabicial actions and may also relieve itching by an independent mechanism. Mild adverse reactions (dermatitis, conjunctivitis) occur occasionally. Crotamiton is available in cream and lotion formulations.

To treat scabies, crotamiton is massaged into the skin of the entire body, starting with the chin and working down. The head and face are treated only if needed. Special attention should be given to skinfolds and creases. Contact with the eyes, mucous membranes, and any regions of inflammation should be avoided. A second application is made 24 hours after the first. A cleansing bath should be taken 48 hours after the second application. If needed, treatment can be repeated in 7 days.

100.2.4 Pyrethrins Plus Piperonyl Butoxide

The combination of pyrethrins with piperonyl butoxide [RID, others] is used to remove pubic lice and head lice. Pyrethrins are the components of this preparation that are toxic to lice. The piperonyl butoxide enhances pyrethrins' action by decreasing the ability of insects to metabolize pyrethrins into inactive products. The combination is active against adult parasites, but not against ova. Pyrethrins undergo little transcutaneous absorption and are one of the safest insecticides available. Principal adverse effects are irritation to the eyes and mucous membranes. Accordingly, contact with these areas should be avoided. Most formulations contain 0.33% pyrethrins and either 2%, 3%, or 4% piperonyl butoxide. Treatment consists of applying the preparation (gel, lotion, shampoo, mousse) to the infested region, followed later by a warm-water rinse. The procedure should be repeated in a week. Nits are removed by combing.

100.2.5 Lindane

100.2.5.1 Actions and Uses

Lindane is absorbed through the chitin shell of adult mites and lice and causes death by inducing convulsions. The drug is also lethal to ova. At one time, lindane was a drug of choice for pediculosis and scabies. However, owing to a risk of seizures, the Food and Drug Administration (FDA) now recommends that lindane be reserved for patients who have not responded to safer drugs (eg, permethrin, malathion). Repeat dosing should be avoided. The drug has been banned in California owing to concerns about contamination of drinking water, rivers, and lakes.

100.2.5.2 Adverse Effects

100.2.5.2.1 Irritation.

Lindane is irritating to the eyes and mucous membranes. Application to the face should be avoided. If contact occurs, the affected area should be flushed with water.

100.2.5.2.2 Convulsions.

Lindane can penetrate the intact skin and, if absorbed in sufficient amounts, can cause convulsions. Convulsions can also result from lindane ingestion. Fortunately, convulsions are rare, resulting most often from drug ingestion or from inappropriate administration. If a seizure develops, it can be controlled with an IV barbiturate (eg, phenobarbital) or with IV diazepam.

The risk of convulsions is highest for infants, children, and patients with pre-existing seizure disorders. Risk is also high for the elderly and for all patients who weigh less than 110 pounds (50 kg). Premature infants are especially vulnerable. Why? Because lindane can penetrate their skin with relative ease, and because limited liver function prevents detoxification of absorbed drug.

To reduce seizure risk, the FDA recommends that lindane *not* be used to treat babies, women who are breast-feeding, and anyone who

- Has used lindane in the past few months
- Has not tried a safer medicine for lice or scabies
- Has a seizure disorder or history of seizures
- Has reacted adversely to lindane in the past
- Has open or crusted sores or extensive areas of broken skin in the treatment region
- Has psoriasis or atopic dermatitis

Giving a second treatment too soon after the first increases seizure risk. How soon is too soon? No one knows what a truly safe interval is. Until we know more, patients should wait several months or more before using lindane again.

100.2.5.3 Preparations and Administration

100.2.5.3.1 Preparations.

Lindane is available in a 1% lotion and a 1% shampoo.

100.2.5.3.2 Administration.

100.2.5.3.2.1 Scabies.

To treat scabies, a thin layer of lotion is applied to the entire body below the head. No more than 30 gm (1 oz) should be used. The drug is removed by washing 8 to 12 hours later. As a rule, only one application is required. Pruritus may persist because of residual insect products. This itching does not indicate a need for additional treatment. If a second treatment is deemed necessary, several months should elapse before doing it.

100.2.5.3.2.2 Head Lice.

To kill head lice and their nits, lindane shampoo (30 to 60 gm) should be worked into dry hair and left in place for no more than 4 minutes. After this, the shampoo should be rinsed off with warm water. Dead nits can be removed with a comb or tweezers. Lindane cream can be employed to treat head lice, but this formulation is less convenient than the shampoo.

100.2.5.3.2.3 Pubic Lice.

The affected region should receive the same treatment employed for head lice. Shampoo is preferred to lotion. One treatment is usually sufficient. Sexual partners should be treated concurrently. Lindane should not be used to treat infestation of the eyelashes by the pubic louse. For this condition, petrolatum ophthalmic ointment is employed.

100.2.5.3.2.4 Body Lice.

Body lice can be killed by applying a thin layer of lindane ointment or cream to affected areas. The drug should be washed off 8 to 12 hours after application.

100.2.6 Ivermectin

Ivermectin [Stromectol] is the only oral medication used for ectoparasitic infestations. The drug kills parasites by disrupting nerve and muscle function—but does not disrupt nerve or muscle function in the host. Ova are not affected. A single dose (200 mcg/kg) can be highly effective

against both mites and lice. However, since the drug does not kill ova, a second dose is often needed. Although ivermectin is highly active against mites and lice, it is not FDA approved for this use. The pharmacology of ivermectin is discussed further in [Chapter 96](#) (Anthelmintics).

100.2.6.1

KEY POINTS

- Pediculosis (infestation with lice) and scabies (infestation with mites) are usually treated with topical drugs.
- Permethrin is the drug of choice for both mites and lice. The 5% cream [Elimite, Acticin] is for mites; the 1% solution [Nix] is for lice.

101 CHAPTER 100 Basic Principles of Cancer Chemotherapy

TIMOTHY McGUIRE

RICH LEHNE

As mortality from infectious diseases has declined, thanks to antimicrobial drugs and public health measures, cancer has emerged as a leading cause of death. The American Cancer Society estimated that 565,650 Americans died from cancer in the year 2008. Only heart disease kills more people. Among women ages 30 to 74, neoplastic diseases lead all other causes of mortality. Among children ages 1 to 14 years, cancer is the leading nonaccidental cause of death. As shown in [Table 100-1](#), among women, the most common cancers are breast, lung, and colorectal. Among men, the most common cancers are prostate, lung, and colorectal.

We have three major modalities for treating cancer: *surgery*, *radiation therapy*, and *drug therapy*. Surgery is the most common treatment for *solid* cancers. In contrast, drug therapy is the treatment of choice for *disseminated* cancers (leukemias, disseminated lymphomas, and metastases) along with several localized cancers (eg, choriocarcinoma, testicular carcinoma). Drug therapy also plays an important role as an adjunct to surgery and irradiation: By suppressing or killing malignant cells that surgery and irradiation leave behind, adjuvant drug therapy can reduce recurrence and improve survival.

Anticancer drugs fall into four major classes: *cytotoxic agents* (ie, drugs that kill cells directly), *hormones and hormone antagonists*, *biologic response modifiers* (eg, immunomodulating agents), and *targeted drugs* (ie, drugs that bind with specific molecules [targets] that promote cancer growth). Of the four classes, the cytotoxic agents are used most often. You should note that the term *cancer chemotherapy* applies *only to the cytotoxic drugs*—it does not apply to the use of hormones, biologic response modifiers, or targeted drugs. In this chapter, our discussion of anticancer drugs pertains almost exclusively to the cytotoxic agents.

The modern era of cancer chemotherapy dates from 1942, the year in which “nitrogen mustards” were first used to treat cancer. Since the introduction of nitrogen mustards, chemotherapy has made significant advances. For patients with some forms of cancer ([Table 100-2](#)), drugs can often be curative. Cancers with a high cure rate include Hodgkin's disease, testicular cancer, and acute lymphocytic leukemia. For many patients whose cancer is not yet curable, chemotherapy can still be of value, offering realistic hopes of palliation and prolonged life. However, although progress in chemotherapy has been encouraging, the ability to cure most cancers with drugs alone remains

elusive. At this time, the major impediment to successful chemotherapy is toxicity of anticancer drugs to normal tissues.

Our principal objectives in this chapter are to examine the major obstacles confronting successful chemotherapy, the strategies being employed to overcome those obstacles, the major toxicities of the chemotherapeutic drugs, and steps that can be taken to minimize drug-induced harm and discomfort. As background for addressing these issues, we begin by discussing (1) the nature of cancer itself and (2) the tissue growth fraction and its relationship to cancer chemotherapy.

^{10...} WHAT IS CANCER?

In the discussion below, we consider properties shared by neoplastic cells as a group. However, although the discussion addresses cancers in general, be aware that the term *cancer* refers to a group of disorders and not to a single disease. The various forms of cancer differ in both phenotype and aggressiveness. In addition, they differ in responsiveness to drugs.

1167

TABLE 100-1 Estimated New Cancer Cases and Deaths, United States, 2008

Type of Cancer	Females		Males	
	New Cases	Deaths	New Cases	Deaths
All types	692,000	271,530	745,180	294,120
Breast	182,460	40,480	1990	450
Prostate			186,320	28,660
Lung and bronchus	100,330	71,030	114,690	90,810
Colon and rectum	71,560	25,700	77,250	24,260
Leukemias and lymphomas	53,580	19,270	65,030	22,950
Endometrium	40,100	7470		
Cervix	11,070	3870		
Ovary	21,650	15,520		
Melanoma of skin	27,530	3020	34,950	5400
Pancreas	18,910	16,790	18,770	17,500
Urinary bladder	17,580	4150	51,230	9950
Kidney	21,260	4910	33,130	8100

101.1.1 Characteristics of Neoplastic Cells

101.1.1.1 Persistent Proliferation.

Unlike normal cells, whose proliferation is carefully controlled, cancer cells undergo unrestrained growth and division. This capacity for persistent proliferation is the most

distinguishing property of malignant cells. In the absence of intervention, cancerous tissues will continue to grow until they cause death.

It was once believed that cancer cells divided more rapidly than normal cells and that this excessive rate of division was responsible for the abnormal growth patterns of cancerous tissues. We now know that this concept is not correct. Division of neoplastic cells is not necessarily rapid: Although some cancers are composed of cells that divide rapidly, others are composed of cells that divide slowly. The correct explanation for the relentless growth of tumors is that *malignant cells are unresponsive to the feedback mechanisms that regulate cellular proliferation in healthy tissue*. Hence, cancer cells are able to continue multiplying under conditions that would suppress further growth and division of normal cells.

101.1.1.2 Invasive Growth.

In the absence of malignancy, the various types of cells that compose a tissue remain segregated from one another; cells of one type do not invade territory that belongs to cells of a different type. In contrast, malignant cells are free of the constraints that inhibit invasive growth. As a result, cells of a solid tumor can penetrate adjacent tissues, thereby allowing the cancer to spread.

101.1.1.3 Formation of Metastases.

Metastases are secondary tumors that appear at sites distant from the primary tumor. Metastases result from the unique ability of malignant cells to break away from their site of origin, migrate to other parts of the body (via the lymphatic and circulatory systems), and then re-implant to form a new tumor.

101.1.1.4 Immortality.

Unlike normal cells, which eventually die, cancer cells can undergo endless divisions. The underlying cause for this difference is *telomerase*, an enzyme that is active in most cancers, and only rarely expressed in normal cells. Telomerase permits repeated division by preserving *telomeres*—the DNA-protein “caps” found on the end of each chromosome. As normal cells divide and differentiate, their telomeres become progressively shorter. When telomeres have lost a critical portion of their length, the cell is unable to keep on dividing. In cancer cells, telomerase continually adds back lost pieces of the telomere, and thereby preserves or extends telomere length. As a result, cancer cells can divide indefinitely.

101.1.2 Etiology of Cancer

The abnormal behavior of cancer cells results from alterations in their DNA. Specifically, malignant transformation results from a combination of activating *oncogenes* (cancer-causing genes) and inactivating *tumor suppressor genes* (genes that prevent replication of cells that have become cancerous). These genetic alterations are caused by chemical carcinogens, viruses, and radiation (x-rays, ultraviolet light, radioisotopes). Malignant transformation occurs in three major stages, called initiation, promotion, and progression. These stages suggest that DNA in cancer cells undergoes a series of small modifications, rather than a single large change. One consequence of malignant transformation is activation of the gene that codes for telomerase.

1168

1169

TABLE 100-2 Some Cancers for Which Drugs May Be Curative

Type of Cancer	Drug Therapy
Hodgkin's lymphoma	Doxorubicin + bleomycin + vinblastine + dacarbazine
Burkitt's lymphoma	Cyclophosphamide + vincristine + methotrexate + doxorubicin + prednisone
Choriocarcinoma	Methotrexate ± leucovorin
Small cell cancer of lung	Etoposide + either cisplatin or carboplatin
Testicular cancer	Cisplatin + etoposide ± bleomycin
Wilms' tumor*	Dactinomycin + vincristine ± doxorubicin ± cyclophosphamide
Ewing's sarcoma*	Cyclophosphamide + doxorubicin + vincristine alternating with etoposide + ifosfamide (with mesna)
Acute myeloid leukemia	Idarubicin + cytarabine
Non-Hodgkin's lymphoma	Rituximab + cyclophosphamide + doxorubicin + vincristine + prednisone
Breast cancer*	Fluorouracil + doxorubicin + cyclophosphamide
Colorectal cancer*	Fluorouracil + leucovorin + oxaliplatin
Acute lymphocytic leukemia	Vincristine + prednisone + asparaginase + daunorubicin or doxorubicin ± cyclophosphamide

* Chemotherapy is combined with surgery and/or radiotherapy in these cancers.

^{10...} THE GROWTH FRACTION AND ITS RELATIONSHIP TO CHEMOTHERAPY

The growth fraction of a tissue is a major determinant of its responsiveness to chemotherapy. Consequently, before we discuss the anticancer drugs, we must first understand the growth fraction. In order to define the growth fraction, we need to review the cell cycle.

^{101.2.1} The Cell Cycle

The cell cycle is the sequence of events that a cell goes through from one mitotic division to the next. As shown in [Figure 100-1](#), the cell cycle consists of four major phases, named G_1 , S, G_2 , and M. (The length of the arrows in the figure is proportional to the time spent in each phase.) For our purpose, we can imagine the cycle as beginning with G_1 , the phase in which the cell prepares to make DNA. Following G_1 , the cell enters S phase, the phase in which DNA synthesis actually takes place. After synthesis of DNA is complete, the cell enters G_2 and prepares for mitosis (cell division). Mitosis occurs next during M phase. Upon completing mitosis, the resulting daughter cells have two options: they can enter G_1 and repeat the cycle, or they can enter the phase known as G_0 . Cells that enter G_0 become mitotically dormant; they do not replicate and are not active participants in the cycle. Cells may remain in G_0 for days, weeks, or even years. Under appropriate conditions, resting cells may leave G_0 and resume active participation in the cycle.

^{101.2.2} The Growth Fraction

In any tissue, some cells are going through the cell cycle, whereas others are “resting” in G_0 . The ratio of proliferating cells to G_0 cells is called the *growth fraction*. A tissue with a large percentage of proliferating cells and few cells in G_0 has

Figure 100-1 The cell cycle.

a *high* growth fraction. Conversely, a tissue composed mostly of G_0 cells has a *low* growth fraction.

^{101.2.3} Impact of Tissue Growth Fraction on Responsiveness to Chemotherapy

As a rule, *chemotherapeutic drugs are much more toxic to tissues that have a high growth fraction than to tissues that have a low growth fraction*. Why? Because most cytotoxic agents are more active against proliferating cells than against cells in G₀. Proliferating cells are especially sensitive to chemotherapy because cytotoxic drugs usually act by disrupting either DNA synthesis or mitosis—activities that only proliferating cells carry out. Unfortunately, toxicity of anticancer drugs is not restricted to cancers: These drugs are also toxic to normal tissues that have a high growth fraction (eg, bone marrow, GI epithelium, hair follicles, sperm-forming cells). 1169
1170

Having established the relationship between growth fraction and drug sensitivity, we can apply this knowledge to predict how specific cancers will respond to chemotherapy. As a rule, *the most common cancers*—solid tumors of the breast, lung, prostate, colon, and rectum—have a *low* growth fraction, and hence tend to *respond poorly*. In contrast, only some rarer cancers—such as acute lymphocytic leukemia, Hodgkin's disease, and certain testicular cancers—have a *high* growth fraction, and hence tend to respond *well*. In practical terms, this means that the most common cancers, which don't respond well to drugs, must be managed primarily with surgery. Only a few cancers can be managed primarily with drugs.

^{10...} OBSTACLES TO SUCCESSFUL CHEMOTHERAPY

Our objective in this section is to examine the major factors that limit success in chemotherapy. Foremost among these is the serious and unavoidable toxicity to normal cells caused by currently available cytotoxic drugs. Other important factors include resistance to chemotherapy and high tumor load (owing to late diagnosis).

^{101.3.1} Toxicity to Normal Cells

Toxicity to normal cells is a major barrier to success in chemotherapy. Injury to normal cells occurs primarily in tissues whose growth fraction is high: bone marrow, GI epithelium, hair follicles, and germinal epithelium of the testes. Drug-induced injury to each of these tissues is discussed in detail below. For now, let's consider injury to normal cells as a group.

Toxicity to normal cells is dose limiting. That is, dosage cannot exceed an amount that produces the maximally tolerated injury to normal cells. Hence, although very large doses of cytotoxic drugs might be able to produce cure, such doses cannot be given because they are likely to kill the patient.

Why are cytotoxic anticancer drugs so harmful to normal tissues? Because these drugs lack *selective toxicity*. That is, *they cannot kill target cells without also killing other cells with which the target cells are in intimate contact*. We first encountered this concept in [Chapter 82](#) (Basic Principles of Antimicrobial Therapy). As noted then, successful antimicrobial therapy is possible because antimicrobial drugs are highly selective in their toxicity. Penicillin, for example, can readily kill invading bacteria while being virtually harmless to cells of the host. This high degree of selective toxicity stands in sharp contrast to the lack of selectivity displayed by cytotoxic anticancer drugs.

Why have we been unable to develop drugs that selectively kill neoplastic cells? Because neoplastic cells and normal cells are very similar. To make a cytotoxic drug that is truly selective, the target cell must have a biochemical feature that normal cells lack. By way of illustration, let's consider penicillin, a drug that kills bacteria by disrupting the bacterial cell wall. Because our cells don't have a cell wall, penicillin can't hurt us. Unfortunately, scientists have yet to identify unique biochemical features that would render cancer cells vulnerable to selective attack. Nonetheless, as discussed below under *Looking Ahead*, there is reason for hope: Our expanding knowledge of cancer biology is revealing potential new targets for anticancer drugs. Exploiting these targets may lead to anticancer drugs that are more selective.

^{101.3.2}Cure Requires 100% Cell Kill

To cure a patient of cancer, we must eliminate virtually every malignant cell. Why? Because just one remaining cell can proliferate and cause relapse. For most patients, 100% cell kill cannot be achieved. Factors that make it difficult to achieve complete cell kill include (1) the kinetics of drug-induced cell kill, (2) minimal participation of the immune system in eliminating malignant cells, and (3) disappearance of cancer symptoms before all cancer cells are gone.

^{101.3.2.1} Kinetics of Drug-Induced Cell Kill.

Killing of cancer cells follows *first-order kinetics*. That is, at any given dose, a drug will kill a *constant percentage* of malignant cells, *regardless of how many cells are actually present*. This means that the dose required to shrink a cancer from 10^3 cells down to 10 cells will be just as big, for example, as the dose required to reduce that cancer from 10^9 cells down to 10^7 cells. Hence, with each successive round of chemotherapy, drug dosage must remain the same, even though the cancer is getting progressively smaller. Accordingly, if treatment is to continue, the patient must be able to tolerate the same degree of toxicity late in therapy that he or she could tolerate when therapy began. For many patients, this is not possible.

101.3.2.2 Host Defenses Contribute Little to Cell Kill.

In contrast to the antimicrobial drugs, anticancer agents receive very little help from host defenses. Therefore, anticancer agents must produce cell kill almost entirely on their own. There are three reasons why. First, because many anticancer drugs are immunosuppressants, these agents can seriously compromise immune function. Second, because cancer cells are so much like normal cells, the immune system generally fails to recognize them as foreign, and hence appropriate for attack. Third, with cancers like lymphomas and leukemias, which involve components of the immune system, the immune system may be compromised by the cancer itself.

101.3.2.3 When Should Treatment Stop?

We have no way of knowing when 100% cell kill has been achieved. As a result, there is no definitive method for deciding just when chemotherapy should stop. As indicated in [Figure 100-2](#), symptoms disappear long before the last malignant cell has been eliminated. Once a cancer has been reduced to less than 1 billion cells, it becomes undetectable by usual clinical methods; all signs of disease are absent, and the patient is considered in complete remission. It is obvious, however, that a patient harboring a million malignant cells is by no means cured. It is also obvious that further chemotherapy is indicated. However, what is not so obvious is just how long therapy should last: Because the patient is already asymptomatic, we have no objective means of determining when to stop treatment. The clinical dilemma is this: If therapy continues too long, the patient will be needlessly exposed to serious toxicity; conversely, if drugs are withdrawn prematurely, relapse will occur.

1170

1171

Figure 100-2 Gompertzian tumor growth curve showing the relationship between tumor size and clinical status.

101.3.3 Absence of Truly Early Detection

Early detection of cancer is rare. Cancer of the cervix, which can be diagnosed with a Pap test, is the primary exception. All other forms of cancer are significantly advanced by the time they have grown large enough for discovery. The smallest detectable cancers are about 1 cm in diameter, have a mass of 1 gm, and consist of about 1 billion cells (see [Fig. 100-2](#)). Detection at this stage cannot be considered early.

Late detection has three important consequences. First, by the time the primary tumor is discovered, metastases may have formed. Second, the tumor will be less responsive to drugs than it would have been at an earlier stage (see below). Third, if the cancer has been present for a long time, the patient may be debilitated by the disease, and therefore less able to tolerate treatment.

Even though *truly* early detection is largely impossible, every effort at *relatively* early detection should be made. Why? Because the smaller a cancer is when treatment begins, the better the chances of long-term survival. Hence, even if a cancer has 1 billion cells when it's detected, that's still far better than a gazillion. Accordingly, the American Cancer Society recommends routine testing for several cancers, including cancers of the prostate, breast, and uterus. [Table 100-3](#) indicates who should be tested, how often, and what test or procedure should be performed. With breast cancer, a yearly mammogram can detect disease before it becomes widely invasive, thereby greatly increasing survival—even though more than a billion cells were present at the time of discovery. Along with routine testing, patients should be counseled about ways to reduce cancer risk, especially avoiding tobacco and excessive exposure to ultraviolet radiation, and receiving an HPV vaccine to protect against cervical cancer (see [Chapter 67](#)).

101.3.4 Solid Tumors Respond Poorly

As noted, solid tumors have a low growth fraction (high percentage of G_0 cells) and hence generally respond poorly to cytotoxic drugs. There are two reasons for low responsiveness. First, G_0 cells do not perform the activities that most anticancer drugs are designed to disrupt. Second, because G_0 cells are not active participants in the cell cycle, they have time to repair drug-induced damage before it can do them serious harm.

Not all solid tumors are equally unresponsive: As a rule, *large tumors are even less responsive than small ones*. This difference occurs because, as solid tumors increase in size, many of their cells leave the cell cycle and enter G_0 , causing the growth fraction to decline. Tumor growth slows, in large part, because blood flow in the tumor core is low, depriving cells of nutrients and

1171

1172

oxygen. The decrease in growth fraction in older tumors is a major reason why therapeutic success is more likely when cancers are detected early. Because the rate of growth declines as a tumor gets larger, the tumor growth curve is said to follow *Gompertzian kinetics* (see [Fig. 100-2](#)).

TABLE 100-3 American Cancer Society Recommendations for the Early Detection of Breast, Colorectal, Prostate, and Cervical Cancers, 2008

Type of Cancer	Recommendation
Breast	Women age 40 and older should have an annual mammogram and an annual clinical breast examination (CBE) by a healthcare professional; a monthly breast self-examination may be done in addition. Ideally, the CBE should occur before the scheduled mammogram. Women ages 20–39 should have a CBE by a healthcare professional every 3 years.
Colon and rectum	Beginning at age 50, men and women should follow one of the examination schedules below: <ul style="list-style-type: none">• A fecal occult blood test (FOBT) or a fecal immunochemical test (FIT) every year, <i>or</i> a flexible sigmoidoscopy (FSIG) every 5 years, <i>or</i>, preferably, both (ie, a FOBT or FIT every year <i>plus</i> a FSIG every 5 years)• A double-contrast barium enema every 5 years• A colonoscopy every 10 years
Prostate [*]	The prostate-specific antigen (PSA) test and the digital rectal examination should be offered annually, beginning at age 50, to men who have a life expectancy of at least 10 years. Men at high risk—African Americans and men with a family history of one or more first-degree relatives diagnosed with prostate cancer at an early age—should begin testing at age 45. Information should be provided to patients about what is known and what is uncertain about the benefits and limitations of early detection and treatment of prostate cancer, so that they can make an informed decision. [†]
Cervix	Cervical cancer screening should begin about 3 years after a woman begins having vaginal intercourse, but no later than age 21. Screening should be done every year (using a conventional Pap test) or every 2 years (using a liquid-based Pap test). At or after age 30, women who have had three normal test results in a row may get screened every 2–3 years (using cervical cytology alone—either conventional or liquid-based Pap tests), or every 3 years (using a human papillomavirus DNA test plus cervical cytology). Women at least 70 years old who have had 3 or more normal Pap tests in the last 10 years (and no abnormal tests in that time) may choose to stop cervical cancer screening, as may women who have had a total hysterectomy.

Adapted from American Cancer Society: Cancer Facts & Figures 2008. Atlanta: American Cancer Society, 2008. (Available at [caonline](#). [AmCancerSoc.org](#))

* In 2008, the U.S. Preventive Services Task Force (USPSTF) recommended against screening for people older than 85, because harms outweigh benefits. For people age 76 to 85, they generally recommended against screening, but did note that a small benefit might be realized for some people.

† In 2002, the USPSTF recommended *against* routine screening for prostate cancer. The USPSTF finds there is good evidence that screening can detect early prostate cancer, but inconclusive evidence that detection improves health outcomes. In 2008, the USPSTF added that, for men *age 75 and older*, the evidence indicates little or no benefit to screening, but clear potential for harm (incontinence, erectile dysfunction, increased mortality).

The drug sensitivity of a solid tumor can be enhanced by *debulking*. When a solid tumor is reduced by surgery or irradiation, many of the remaining cells leave G₀ and re-enter the cell cycle, thereby increasing their sensitivity to chemotherapy. This phenomenon is known as *recruitment*. Because of recruitment, chemotherapy can be very useful as an adjunct to surgery or irradiation, even though drugs may have been largely ineffective before debulking was done.

101.3.5 Drug Resistance

During the course of chemotherapy, cancer cells can develop resistance to the drugs used against them. Drug resistance can be a significant cause of therapeutic failure. Mechanisms of resistance include reduced drug uptake, increased drug efflux, reduced drug activation, reduced target molecule sensitivity, and increased repair of drug-induced damage to DNA.

Cellular production of a drug transport molecule, known as *P-glycoprotein*, can confer *multiple drug resistance* upon cells. P-glycoprotein is a large molecule that spans the cytoplasmic membrane and pumps drugs out of the cell. Induction of P-glycoprotein synthesis during exposure to a single anticancer drug produces cross-resistance to agents in other drug classes. Several drugs, including cyclosporine, have been used investigatively to inhibit the P-glycoprotein pump and reverse multiple drug resistance.

Drug resistance results from a change in DNA. Mutation to a drug-resistant form is a spontaneous event, and is not caused by the anticancer drugs themselves. However, although drugs do not *cause* the mutations that render cells resistant, drugs do *create selection pressure* favoring the drug-resistant mutants. That is, by killing drug-sensitive cells, anticancer agents create a competition-free environment in which drug-resistant mutants can flourish. This is the same phenomenon we encountered in our discussion of antibacterial drugs.

1172

1173

Because the presence of anticancer agents favors the growth of drug-resistant clones, as therapy proceeds, the number of resistant cells will increase. Since patients are usually exposed to drugs over an extended time, therapeutic failure owing to drug resistance is a significant problem. As discussed below, using a combination of drugs can help overcome resistance.

^{101.3.6} Heterogeneity of Tumor Cells

Tumors do not consist of a single population of identical cells. Rather, owing to ongoing mutation, tumors are composed of subpopulations of dissimilar cells. These subpopulations can differ in morphology, growth rate, and metastatic ability. More importantly, they can differ in responsiveness to drugs—primarily because of increased resistance. As a tumor ages, cellular heterogeneity increases.

^{101.3.7} Limited Drug Access to Tumor Cells

Because of a tumor's location or blood supply, drugs may have limited access to its cells. Large solid tumors have poor vascularization, especially near the core. Hence, cells within these tumors are difficult for drugs to reach. Similarly, tumors of the central nervous system (CNS) are hard to reach because it is difficult for most anticancer drugs to cross the blood-brain barrier.

^{10...} STRATEGIES FOR ACHIEVING MAXIMUM BENEFITS FROM CHEMOTHERAPY

^{101.4.1} Intermittent Chemotherapy

The ultimate goal of chemotherapy is to produce 100% kill of neoplastic cells while causing limited injury to normal tissues—especially the bone marrow and GI epithelium. Intermittent therapy is the primary technique for achieving this goal. When cytotoxic anticancer drugs are administered intermittently, normal cells have time to repopulate between rounds of therapy. However, for this approach to succeed, one obvious requirement must be met: *Normal cells must repopulate faster than malignant cells*. If malignant cells grow back faster than normal cells, there can be no reduction in tumor burden between treatment rounds. The successful use of intermittent therapy is depicted in [Figure 100-3](#).

101.4.2 Combination Chemotherapy

Chemotherapy employing a combination of drugs is generally much more effective than chemotherapy with just one drug. Accordingly, most patients are treated with two or more agents.

Figure 100-3 Recovery of critical normal cells during intermittent chemotherapy. Cancer cells and normal cells (eg, cells of the bone marrow) are killed each time drugs are given. In the interval between doses, both types of cells proliferate. Because, in this example, normal cells repopulate faster than the cancer cells, normal cells are able to recover entirely between doses, whereas regrowth of the cancer cells is only partial. As a result, with each succeeding round of treatment, the total number of cancer cells becomes smaller, whereas the number of normal cells remains within a tolerable range. Note that differential loss of malignant cells is possible only if these cells repopulate more slowly than the normal cells. If cancer cells grow back as fast as normal cells do, intermittent chemotherapy will fail.

101.4.2.1 Benefits of Drug Combinations

Combination chemotherapy offers three advantages: (1) suppression of drug resistance, (2) increased cancer cell kill, and (3) reduced injury to normal cells (at any given level of anticancer effect).

101.4.2.1.1 Suppression of Drug Resistance.

Drug resistance occurs less frequently with multiple-drug therapy than with single-drug therapy. To understand why, we need to recall that resistance is acquired through random mutational events. The probability of a cell undergoing two or more mutations, and therefore developing resistance to a combination of drugs, is smaller than the probability of a cell undergoing the single mutation needed for resistance to one drug. Because drug resistance is reduced with combination chemotherapy, the chances of therapeutic success are increased.

101.4.2.1.2 Increased Cancer Cell Kill.

If we administer several anticancer drugs, each with a different mechanism of action, we will kill more malignant cells than if we use only one drug. Therapeutic effects are enhanced because the combination attacks the cancer in two or more ways, not just one. Greater cell kill is especially likely if a drug-resistant subpopulation of cells is present. The superiority of drug combinations over single-drug therapy is illustrated by the data in [Table 100-4](#).

101.4.2.1.3 Reduced Injury to Normal Cells.

By using a combination of drugs *that do not have overlapping toxicities*, we can achieve a greater anticancer effect than we could *safely* achieve using any of the agents alone. The data in [Table 100-5](#) indicate why. The table summarizes responses to two drugs—vincristine and cyclophosphamide—when given alone and in combination. Both drugs kill malignant cells, but they act by different mechanisms: cyclophosphamide damages DNA, whereas vincristine blocks mitosis. Furthermore, these drugs have different dose-limiting toxicities: Cyclophosphamide causes *neutropenia*, whereas vincristine causes *neuropathy*. In the table, the intensity of effects is indicated by plus (+) symbols—the more plusses, the more intense the response. With either drug, ++ represents the maximum degree of toxicity that can be tolerated. When administered alone in doses that produce ++ toxicity, each drug produces an anticancer effect of ++ intensity—the greatest therapeutic effect that we can safely achieve with either drug by itself. Now let's consider the effect of combining these drugs, giving each in its maximally tolerated dose. The total anticancer effect of the combination is +++, twice

1173
1174

the effect that could be achieved safely with either agent alone. Because the toxicities of these agents do not overlap, overall toxicity of the combination remains at a tolerable level—although the patient is now exposed to two kinds of toxicity rather than one.

**TABLE 100-4 Single-Drug Treatment Versus Combination
Chemotherapy**

Type of Cancer	Method of Treatment and Drugs Employed	Percentage of Patients with Complete Remission
Acute lymphocytic leukemia of childhood	<i>Single-Drug Therapy</i>	
	Daunorubicin	38
	Prednisone	63
	Vincristine	57
	<i>Combination Chemotherapy</i>	
	Prednisone + vincristine	90
Hodgkin's disease	Prednisone + vincristine + daunorubicin	97
	<i>Single-Drug Therapy</i>	
	Vincristine	<10
	Prednisone	<5
	Procarbazine	<10
	Mechlorethamine	20
	<i>Combination Chemotherapy</i>	
	Vincristine + prednisone + mechlorethamine + procarbazine	81
Data from DeVita VT, Young RC, Canellos GP: Combination versus single agent chemotherapy: A review of the basis for selection of drug treatment of cancer. Cancer 35:98, 1975.		

TABLE 100-5 Effects of Cyclophosphamide and Vincristine Alone and in Combination

Therapeutic Regimen	Anticancer Effect	Toxicity	
		Neutropenia	Neurotoxicity
Cyclophosphamide	++	++	0
Vincristine	++	0	++
Cyclophosphamide + vincristine	++++	++	++

101.4.2.2 Guidelines for Drug Selection

From the preceding, we can extract three guidelines for selecting drugs to use in combination: (1) each drug should be effective by itself, (2) each drug should have a different mechanism of action, and (3) the drugs should have minimally overlapping toxicities.

101.4.3 Optimizing Dosing Schedules

The administration schedule is an important determinant of treatment outcome. The experiment summarized in [Table 100-6](#) provides a dramatic illustration. In this experiment, two groups of mice were inoculated with cancer cells and then treated with cytarabine. Mice in group I received a *single large dose* of cytarabine on days 2, 6, 10, and 14 after being inoculated. The mice in group II were treated on the same days as the mice in group I, but, rather than receiving one large dose of cytarabine, they were given *eight small doses*, one every 3 hours. By the end of the study, all of the group II mice were cured. In stark contrast, all of the group I mice were dead. Since the two groups had the same disease burden and were given the same drug, we must conclude that the life-and-death difference was due to the dosing schedules employed.

To understand these results, we need to know two properties of cytarabine: (1) the drug kills cells by disrupting DNA synthesis, and (2) it undergoes rapid inactivation. Because cytarabine acts by disrupting DNA synthesis, it can only affect cells during S phase. Because the drug is rapidly inactivated, and because many cells will not be in S phase during the short time before inactivation occurs, many cells will escape injury following each dose. The group I mice died because giving just one large dose every 4 days did not maintain active drug in the body for a time sufficient to catch all cancer cells as they cycled through S phase. Because the group II mice received multiple doses over a 24-hour period on each of 4 days, the presence of active drug was

1174
1175

sustained. Hence, the chance of cancer cells being in S phase while active drug was present was greatly increased, thereby leading to enhanced cell kill with resultant cure.

TABLE 100-6 Effect of Dosing Schedule on Therapeutic Response

Experimental Group	Dosage Size	Dosing Schedule	Mice Surviving
I	240 mg/kg	1 dose/day*	None
II	15 mg/kg	8 doses/day*	100%

* Cytarabine was administered on days 2, 6, 10, and 14 after mice were inoculated with leukemia cells. See text for further details.

The message from this experiment is this: Selection of the right drugs for cancer therapy is only one of the requirements for success; those drugs must also be administered according to schedules that will maximize beneficial effects. Dosing schedules are especially critical for drugs that, like cytarabine, act during a specific phase of the cell cycle.

101.4.4 Regional Drug Delivery

By using special techniques for drug delivery, we can increase drug access to tumors, thereby increasing cell kill and reducing systemic toxicity.

101.4.4.1 Intra-arterial Delivery.

Local intra-arterial infusion can be used to treat solid tumors. This technique has the advantage of establishing a high concentration of drug in the vicinity of the tumor while minimizing toxicity to the rest of the body. Specific routes include carotid artery delivery (for brain tumors) and hepatic artery delivery (for liver metastases). Clearly, intra-arterial therapy is suitable only for localized disease.

101.4.4.2 Intrathecal Delivery.

As noted, many anticancer agents are unable to cross the blood-brain barrier, and therefore cannot reach malignant cells in the CNS. To enhance therapy of CNS cancers, drugs can be administered intrathecally (by injection directly into the subarachnoid space). This technique bypasses the blood-brain barrier, thereby giving drugs better access to cells within the CNS.

101.4.4.3 Other Specialized Routes.

Anticancer agents can be administered via the portal vein to treat liver metastases, and directly into the bladder to treat bladder cancer. Neoplasms located in the pleural and peritoneal cavities can be treated by direct intracavitary drug administration. As discussed in [Chapter 101](#), carmustine, a drug for brain tumors, is available in a wafer that is implanted in the brain to kill cancer cells left behind following surgical removal of a tumor.

10... MAJOR TOXICITIES OF CHEMOTHERAPEUTIC DRUGS

The agents used for cancer chemotherapy constitute our most toxic group of medicines. Serious injury occurs most often to tissues that have a high growth fraction (bone marrow, GI epithelium, hair follicles, sperm-forming cells). In the discussion below, we consider the more common toxicities of the *cytotoxic* anticancer drugs along with steps that can be taken to minimize harm and discomfort.

101.5.1 Bone Marrow Suppression

Chemotherapeutic drugs are highly toxic to the bone marrow, a tissue with a high proportion of proliferating cells. Myelosuppression reduces the number of circulating neutrophils, platelets, and erythrocytes. Loss of these cells has three major consequences: (1) infection (from loss of neutrophils); (2) bleeding (from loss of platelets); and (3) anemia (from loss of erythrocytes).

101.5.1.1 Neutropenia

Neutrophils (neutrophilic granulocytes) are white blood cells that play a critical role in fighting infection. In patients with neutropenia (a reduction in circulating neutrophils), both the incidence and severity of infection are increased. Infections that are normally benign (eg, candidiasis) can become life threatening. Infection secondary to neutropenia is one of the most serious complications of chemotherapy.

With most anticancer drugs, onset of neutropenia is rapid and recovery develops relatively quickly. Neutropenia begins to develop a few days after dosing, and the lowest neutrophil count, called the *nadir*, occurs between days 10 and 14. Neutrophil counts then recover a week or so later. Patients are at highest risk during the nadir. Accordingly, special care should be taken to prevent infection.

With some anticancer drugs, neutropenia is *delayed*. Neutrophil counts begin to fall in 1 to 2 weeks, and reach their nadir between weeks 3 and 4. Full recovery may not occur until after week 7.

Neutrophil counts must be monitored. Normal counts range from 2500 to 7000 cells/mm³. If neutropenia is substantial (absolute neutrophil count below 500/mm³), chemotherapy should be withheld until neutrophil counts return toward normal.

Lack of neutrophils confounds the diagnosis of infection. Why? Because the usual signs of infection (eg, pus, abscesses, infiltrates on the chest x-ray) depend on neutrophils being present. In the absence of neutrophils, *fever* is the principal early sign of infection.

Patients must be their own first line of defense against infection. They should be made aware of their elevated risk of infection and taught how to minimize contagion. They should be informed that fever may be the only indication of infection and instructed to notify the physician immediately if fever develops. Because infection is commonly acquired through contact with other people, hospitalized patients should be instructed to refuse direct contact with anyone who has not washed his or her hands in the patient's presence. This rule applies not only to visiting friends and relatives but also to nurses, physicians, and all other hospital staff. The normal flora of the body is a major source of infection; the risk of acquiring an infection with these microbes can be reduced by daily examination and cleansing of the skin and oral cavity.

Hospitalization of the infection-free neutropenic patient is controversial. Some physicians feel that hospitalization *increases* the risk of acquiring a serious infection. Why? Because hospitals harbor drug-resistant microbes, which can make hospital-acquired (nosocomial) infections especially difficult to treat. Accordingly, these physicians recommend that neutropenic patients stay at home as long as they remain infection free.

If neutropenic patients *are* hospitalized, every precaution must be taken to prevent nosocomial infection. Patients should be given an isolation room and monitored frequently for fever.

1175

1176

Certain foods (eg, salads) abound in pathogenic bacteria and must be avoided.

When a neutropenic patient develops an infection, immediate and vigorous intervention is required. Specimens for culture should be taken to determine the identity and drug sensitivity of the infecting organism. While awaiting reports on the cultures, empiric therapy with IV antibiotics should be instituted. Initial therapy is usually done with a single drug active against *Pseudomonas* and other gram-negative bacteria. Options include ceftazidime, imipenem, and

moxalactam. If the patient develops sepsis, an aminoglycoside (eg, tobramycin, amikacin) is added. If the patient remains febrile, vancomycin is added (for gram-positive coverage).

Colony-stimulating factors can minimize neutropenia. Two preparations are available: *granulocyte colony-stimulating factor* (G-CSF, filgrastim) and *granulocyte-macrophage colony-stimulating factor* (GM-CSF, sargramostim). Both drugs act on the bone marrow to enhance granulocyte (neutrophil) production. Colony-stimulating factors can decrease the incidence, magnitude, and duration of neutropenia. As a result, they can decrease the incidence and severity of infection as well as the need for IV antibiotics and hospitalization. The basic pharmacology of G-CSF and GM-CSF is discussed in [Chapter 55](#).

101.5.1.2 Thrombocytopenia

Bone marrow suppression can cause thrombocytopenia (a reduction in circulating platelets), thereby increasing the risk of serious bleeding. Bleeding from the nose and gums is relatively common. Bleeding from the gums can be reduced by avoiding vigorous toothbrushing. Drugs that promote bleeding (eg, aspirin, anticoagulants) should not be used. When a mild analgesic is required, acetaminophen, which does not promote bleeding, is preferred to aspirin. For patients with severe thrombocytopenia, platelet infusions are the mainstay of treatment. As discussed in [Chapter 55](#), platelet production can be stimulated with *oprelvekin* [Neumega]. However, owing to limited efficacy and flu-like reactions, oprelvekin is not used often.

Caution should be exercised when performing procedures that might promote bleeding. Intravenous needles should be inserted with special care, and intramuscular injections should be avoided. Blood pressure cuffs should be applied cautiously, because overinflation may cause bruising or bleeding.

101.5.1.3 Anemia

Anemia is defined as a reduction in the number of circulating erythrocytes (red blood cells). Although anticancer drugs can suppress erythrocyte production, anemia is much less common than neutropenia or thrombocytopenia. Why? Because circulating erythrocytes have a long life span (120 days), which usually allows erythrocyte production to recover before levels of existing erythrocytes fall too low.

If anemia does develop, it can be treated with a transfusion or with erythropoietin (*epoetin alfa* or *darbepoetin alfa*), a hormone that stimulates production of red blood cells. Because transfusions require hospitalization, whereas epoetin can be administered at home, epoetin therapy can spare the patient inconvenience. However, erythropoietin has the drawback of

being expensive. In addition, it cannot be used in patients with leukemias and other myeloid malignancies, because it can stimulate proliferation of these cancers. The basic pharmacology of erythropoietin is discussed in [Chapter 55](#).

101.5.2 Digestive Tract Injury

The epithelial lining of the GI tract has a very high growth fraction, and hence is exquisitely sensitive to cytotoxic drugs. Stomatitis and diarrhea are common. Severe GI injury can be life threatening.

101.5.2.1 Stomatitis.

Stomatitis (inflammation of the oral mucosa) often develops a few days after the onset of chemotherapy and may persist for 2 or more weeks after treatment has ceased. Inflammation can progress to denudation and ulceration, and is often complicated by infection. Pain can be severe, inhibiting eating, speaking, and swallowing. Management includes good oral hygiene and a bland diet. Topical antifungal drugs may be needed to control infection with *Candida albicans*. For patient with mild stomatitis, pain can be managed with a mouthwash containing a topical anesthetic (eg, lidocaine) plus an antihistamine (eg, diphenhydramine). For patients with severe stomatitis, a systemic opioid is needed for pain. In some cases, stomatitis is so severe that chemotherapy may need to be interrupted. For patients being treated for hematologic malignancies, *palifermin* [Kepivance] can decrease the severity of stomatitis (see [Chapter 79](#)).

101.5.2.2 Diarrhea.

By injuring the epithelial lining of the intestine, anticancer drugs can impair absorption of fluids and other nutrients, thereby causing diarrhea. Diarrhea can be reduced with oral loperamide, a nonabsorbable opioid that slows gut motility by activating local opioid receptors.

101.5.3 Nausea and Vomiting

Nausea and vomiting are common sequelae of cancer chemotherapy. These responses, which result in part from direct stimulation of the chemoreceptor trigger zone, can be both immediate and dramatic, and may persist for hours or even days. In some cases, discomfort is so great as to prompt refusal of further treatment.

You should appreciate that nausea and vomiting associated with chemotherapy are much more severe than with other medications. Hence, whereas these reactions are generally unremarkable

with most drugs, they must be considered major and characteristic toxicities of anticancer drugs. The emetogenic potential of several agents is indicated in [Table 100-7](#).

Nausea and vomiting can be reduced by premedication with antiemetics. These drugs offer three benefits: (1) reduction of anticipatory nausea and vomiting, (2) prevention of dehydration and malnutrition secondary to frequent nausea and vomiting, and (3) promotion of compliance with chemotherapy by reducing discomfort. Combinations of antiemetics are more effective than single-drug therapy. The regimen of choice for patients taking highly emetogenic drugs consists of *aprepitant* [Emend], *dexamethasone*, and a *serotonin antagonist*, such as *ondansetron* [Zofran]. The antiemetic drugs and their use in chemotherapy are discussed at length in [Chapter 79](#).

101.5.4 Other Important Toxicities

101.5.4.1 Alopecia.

Reversible alopecia (hair loss) results from injury to hair follicles. Alopecia can occur with	1176
most cytotoxic anticancer drugs. Hair loss begins 7 to 10 days after the onset of treatment and	1177
becomes maximal in 1 to 2 months. Regeneration begins 1 to 2 months after the last course of treatment.	

TABLE 100-7 Emetogenic Potential of Selected Cytotoxic Anticancer Drugs

Severe	Moderate
Cisplatin	Cytarabine
Dacarbazine	Procarbazine
Mechlorethamine	Mitomycin
Streptozocin	Methotrexate (high doses)
Moderately Severe	Mild
Cyclophosphamide	Etoposide
Ifosfamide	Fluorouracil
Doxorubicin	Hydroxyurea
Nitrosourea	Bleomycin
Dactinomycin	Vinblastine
	Vincristine
	Chlorambucil
	Methotrexate (low doses)

While alopecia is not dangerous, it is nonetheless very upsetting. In fact, for many cancer patients, alopecia is second only to vomiting as their greatest treatment-related fear. If drugs are expected to cause hair loss, the patient should be forewarned. For patients who choose to wear a hairpiece, one should be selected before hair loss occurs. Hairpieces are tax deductible as medical expenses and are covered by some insurance plans.

101.5.4.2 Reproductive Toxicity.

The developing fetus and the germinal epithelium of the testes have high growth fractions. As a result, both are highly susceptible to injury by cytotoxic drugs, especially the alkylating agents. These drugs can interfere with embryogenesis, causing death of the early embryo. They may also cause fetal malformation. Risk is highest during the first trimester, and hence chemotherapy should be avoided during this time, if possible. Women undergoing chemotherapy should be warned against becoming pregnant. If pregnancy occurs, the possibility of terminating the pregnancy should be discussed—in light of the knowledge that, although there is risk, many patients have given birth to healthy babies. Drug effects on the

ovaries may result in amenorrhea, menopausal symptoms, and atrophy of the vaginal epithelium.

Cytotoxic drugs can cause irreversible sterility in males. Men should be forewarned and counseled about sperm banking.

101.5.4.3 Hyperuricemia.

Hyperuricemia is defined as an excessive level of uric acid in the blood. Uric acid, a compound with low solubility, is formed by the breakdown of DNA following cell death. Hyperuricemia is especially common following treatment for leukemias and lymphomas (because therapy results in massive cell kill). The major concern with hyperuricemia is injury to the kidneys secondary to deposition of uric acid crystals in renal tubules. The risk of crystal formation can be reduced by increasing fluid intake. In patients with leukemias and lymphomas, in whom hyperuricemia is likely, prophylaxis with *allopurinol* is the standard of care. (As discussed in [Chapter 73](#), allopurinol prevents hyperuricemia by inhibiting xanthine oxidase, an enzyme involved in converting nucleic acids to uric acid.) If hyperuricemia develops despite use of allopurinol, it can be managed with *rasburicase*, an enzyme that catalyzes uric acid degradation (see [Chapter 106](#)).

101.5.4.4 Local Injury from Extravasation of Vesicants.

Certain anticancer drugs, known as *vesicants*, are highly chemically reactive. These drugs can cause severe local injury if they make direct contact with tissues. Vesicants are administered IV, usually into a central line (because rapid dilution in venous blood minimizes the risk of injury). When a peripheral line is used, administration is by IV push through a sidearm in a freely flowing IV line. Sites of previous irradiation should be avoided. Extreme care must be exercised to prevent extravasation, because leakage can produce high local concentrations, resulting in prolonged pain, infection, and loss of mobility. Severe injury can lead to necrosis and sloughing, requiring surgical débridement and skin grafting. If extravasation occurs, the infusion should be stopped immediately. Vesicants should be administered only by clinicians specially trained to handle them safely.

101.5.4.5 Unique Toxicities.

In addition to the toxicities discussed above, which generally apply to the cytotoxic drugs as a group, some agents produce unique toxicities. For example, daunorubicin can cause serious harm to the heart, cisplatin can injure the kidneys, and vincristine can injure peripheral nerves. Special toxicities of individual drugs are considered in [Chapters 101](#) and [102](#).

101.5.4.6 Carcinogenesis.

Along with their other adverse actions, anticancer drugs have one final and ironic toxicity: These drugs, which are used to treat cancer, have caused cancer in some patients. Cancer results from drug-induced damage to DNA, and is most likely with alkylating agents. Cancers caused by anticancer drugs may take many years to appear and are hard to treat.

10... MAKING THE DECISION TO TREAT

From the preceding discussion of toxicities, it is clear that cytotoxic anticancer drugs can cause great harm. Given the known dangers of these drugs, we must ask why such toxic substances are given to sick people at all. The answer lies with the primary rule of therapeutics, which states that the benefits of treatment must outweigh the risks. For most patients undergoing chemotherapy, the conditions of this rule are met. That is, although the toxicities of the anticancer drugs can be significant, the potential benefits (cure, prolonged life, palliation) justify the risks. However, the desirability of treating cancer with drugs is not always obvious. There are patients whose chances of being helped by chemotherapy are remote, while the risk of serious toxicity is high. Because the potential benefits for some patients are small and the risks are large, the decision to institute chemotherapy must be made with care.

Before a decision to treat can be made, the patient must be given some idea of the benefits the proposed therapy might offer. Three basic benefits are possible: cure, prolongation of life, and palliation. For treatment to be justified, there should be reason to believe that at least one of these benefits will be forthcoming. If a patient cannot be offered some reasonable hope of cure, prolonged life, or palliation, it would be difficult to justify treatment.

The most important factors for predicting the outcome of chemotherapy are (1) the general health of the patient and (2) the responsiveness of the type of cancer the patient has. General health status is assessed by measuring performance status, frequently using the Karnofsky Performance Scale ([Table 100-8](#)). A Karnofsky score of less than 40 indicates the patient is debilitated and not likely to tolerate the additional stress of chemotherapy. Accordingly, patients with a low Karnofsky rating should not receive anticancer drugs—unless their cancer is known to be especially responsive.

1177

1178

TABLE 100-8 Karnofsky Performance Scale

Definition	Percentage	Criteria
Able to carry on normal activity and work; no special care needed	100	Normal; no complaints; no evidence of disease
	90	Able to carry on normal activity; minor signs or symptoms of disease
	80	Normal activity with effort; some signs or symptoms of disease
Unable to work; able to live at home and care for most personal needs; a varying amount of assistance needed	70	Cares for self; unable to carry on normal activity or do active work
	60	Requires occasional assistance; able to care for most needs
	50	Requires considerable assistance and frequent medical care
Unable to care for self; requires equivalent of institutional or hospital care; disease may be progressing rapidly	40	Disabled; requires special care and assistance
	30	Severely disabled; hospitalization is indicated although death not imminent
	20	Very sick, hospitalization necessary; active supportive treatment necessary
	10	Moribund; fatal processes progressing rapidly
	0	Dead

TABLE 100-9 Responsiveness of Some Cancers to Chemotherapy

Responsiveness to Chemotherapy	Type of Cancer	Probable Benefits of Chemotherapy
High	Hodgkin's disease	Cure or prolongation of life
	Aggressive NHL	
	Acute myeloid leukemia	
	Testicular cancer	
	Ovarian cancer	
	Acute lymphocytic leukemia	
	Choriocarcinoma	
	Wilms' tumor	
	Ewing's sarcoma	
Moderate	Breast cancer	Prolongation of life; palliation
	Colorectal cancer	
	Osteosarcoma	
	Chronic lymphocytic leukemia	
	Bladder cancer	
	Multiple myeloma	
	Prostate carcinoma	
Minimal	Cervical cancer	Palliation; minimal prolongation of life
	Hepatocellular cancer	
	Melanoma	
	Pancreatic cancer	
	Renal cancer	
NHL = non-Hodgkin's lymphoma.		

The responsiveness of some common cancers is indicated in [Table 100-9](#). Patients with highly responsive types of cancer should almost always be treated, even if their Karnofsky score is low. In

contrast, patients with minimally responsive types of cancer should be treated only after careful consideration, to avoid the discomforts of a course of treatment that has little to offer.

An important requirement for deciding in favor of chemotherapy is that the impact of treatment be measurable. That is, there must be some objective means of determining the cancer's response to drugs. For solid tumors, we should be able to measure a decrease in tumor size (or at least inhibition of further growth). For hematologic cancers, we should be able to measure a decrease in neoplastic cells in blood and bone marrow. If we have no way to measure the response of a cancer, then we have no way of knowing if treatment has done any good. If we cannot determine that drugs are doing something beneficial, there is little justification for giving them.

1178

1179

Clearly, not all patients are candidates for chemotherapy. The decision to institute treatment must be individualized. Patients should be informed as accurately as possible about the potential risks and benefits of the proposed therapy. When the decision to treat is made, it should be the result of collaboration between the patient, family, and physician, and should reflect a conviction on the part of the patient that, within his or her set of values, the potential benefits outweigh the inherent risks.

10... LOOKING AHEAD

Does the future offer hope of developing drugs that can cure people who can't be cured today? This question can be cautiously answered in the affirmative. There is no theoretical reason to believe that cancers are inherently incapable of cure. On the contrary, there is good reason to believe that cancers are, in fact, curable. New insights into tumor biology are suggesting many new ways to attack cancer cells. Three approaches are especially exciting: cancer vaccines, angiogenesis inhibitors, and telomerase inhibitors. Custom-made vaccines using the patient's own cancer cells can intensify immune attack against the cancer. Angiogenesis inhibitors can block the growth of new blood vessels into solid tumors, thereby starving the tumor. Telomerase inhibitors offer the possibility of a "magic bullet" that can block the endless proliferation of cancer cells, while leaving normal cells unharmed. Other important approaches include inhibition of epidermal growth factor, inhibition of various cellular kinases, and inhibition of oncogenes. These areas of research and others may finally lead to drugs that have the same degree of selective toxicity for cancer as, for example, penicillin G has for gram-positive bacteria. Drugs with this degree of selectivity will offer a cure for neoplastic diseases—and will provide that cure without the toxicities associated with today's drugs. It is not completely naive to believe that such drugs will eventually be available. In the meantime, we can take heart in the progress achieved so far: Drugs like trastuzumab [Herceptin] (for breast cancer) and imatinib [Gleevec] (for chronic myeloid leukemia and GI stromal tumors) are both highly effective and much less toxic than traditional chemotherapeutic agents.

101.7.1

KEY POINTS

- Cancer cells are characterized by persistent proliferation, invasive growth, and the ability to form metastases.
- Cancer can be treated with three basic modalities: surgery, radiation therapy, and drug therapy.
- Agents used for drug therapy fall into two main groups (1) cytotoxic agents and (2) noncytotoxic agents, such as hormones, immunomodulators, and targeted drugs.
- Surgery and/or irradiation are the treatments of choice for most solid tumors.
- Drugs are the treatment of choice for disseminated cancers (leukemias, disseminated lymphomas, widespread metastases). Drugs are also used as adjuvants to surgery and irradiation to kill malignant cells that surgery and irradiation leave behind.
- The cell cycle has four major phases: G_1 , in which cells prepare to synthesize DNA; S, in which cells synthesize DNA; G_2 , in which cells prepare for mitosis (division); and M, in which cells actually divide. Following mitosis, the resulting daughter cells may either enter G_1 and repeat the cycle, or enter G_0 and become mitotically dormant.
- The growth fraction of a tissue is defined as the ratio of proliferating cells to cells in G_0 .
- Tissues with a large percentage of proliferating cells and few cells in G_0 have a high growth fraction. Conversely, tissues composed mostly of G_0 cells have a low growth fraction.
- Cytotoxic anticancer drugs are more toxic to cancers that have a high growth fraction than to cancers that have a low growth fraction. Why? Because cytotoxic anticancer drugs are more active against proliferating cells than against cells in G_0 .
- The most common cancers—solid tumors of the breast, lung, prostate, colon, and rectum—have a low growth fraction, and hence respond poorly to drugs. In contrast, only some rarer cancers—such as acute lymphocytic leukemia, Hodgkin's disease, and certain testicular cancers—have a high growth fraction, and hence tend to respond well.
- To cure a patient of cancer, we must produce 100% cell kill, which is rare with chemotherapy alone.

- Killing of cancer cells follows first-order kinetics. That is, at any given dose, drugs kill a constant *percentage* of malignant cells, regardless of how many cells are present.
- Over the course of chemotherapy, cancer cells often become drug resistant, thereby decreasing the chance of success.
- The purpose of intermittent chemotherapy is to allow normal cells to repopulate between rounds of treatment. Unfortunately, if the cancer cells repopulate as fast as (or faster than) normal cells, there will be no reduction in tumor burden with each round of treatment, and hence treatment will fail.
- Multidrug chemotherapy is generally much more effective than single-drug therapy. Why? Because combination therapy can (1) suppress drug resistance, (2) increase cell kill, and (3) reduce injury to normal cells (at any given level of anticancer effect).
- Ideally, the drugs used in combination therapy should have (1) different mechanisms of action, (2) minimally overlapping toxicities, and (3) good efficacy when used alone.
- For drugs that act during a specific phase of the cell cycle, selecting the right dosing schedule is critical to success.
- Toxicity to normal tissues is the major obstacle to successful therapy with cytotoxic anticancer drugs.

1179

- Cytotoxic anticancer drugs injure normal tissue because these drugs lack selective toxicity.
- As a rule, serious toxicity occurs to normal tissues that have a high growth fraction (ie, bone marrow, GI epithelium, hair follicles, sperm-forming cells).
- Myelosuppression (toxicity to bone marrow) can reduce the number of neutrophils, platelets, and erythrocytes, thereby posing a risk of infection (from loss of neutrophils), bleeding (from loss of platelets), and anemia (from loss of erythrocytes).
- Loss of neutrophils and platelets during chemotherapy is common; significant loss of erythrocytes is relatively rare, but can happen with certain drugs (eg, cisplatin).
- In patients taking myelosuppressive drugs, neutrophil counts must be monitored. If neutropenia is substantial (absolute neutrophil count below $500/\text{mm}^3$), the next round of chemotherapy should be delayed.

1180

- When a neutropenic patient develops an infection, immediate and vigorous intervention is required. Until lab reports on the identity and drug sensitivity of the infecting organism are available, empiric therapy with IV antibiotics should be instituted.
- Neutropenia can be minimized by treatment with granulocyte colony-stimulating factor or granulocyte-macrophage colony-stimulating factor, both of which act on the bone marrow to increase neutrophil production.
- By injuring the epithelial lining of the GI tract, anticancer drugs often cause stomatitis and diarrhea.
- Many anticancer drugs cause moderate to severe nausea and vomiting, in part by stimulating the chemoreceptor trigger zone.
- Nausea and vomiting can be reduced by premedication with antiemetics. The combination of aprepitant, dexamethasone, and ondansetron is especially effective.
- Anticancer drugs often injure hair follicles, thereby causing alopecia (hair loss). Patients who want to wear a hairpiece should select one before hair loss occurs.
- Anticancer drugs can cause fetal malformation and death. Accordingly, women undergoing chemotherapy should be warned against becoming pregnant.
- Anticancer drugs can cause irreversible male sterility. Accordingly, men undergoing chemotherapy should be counseled about possible sperm banking.
- Chemotherapy can cause hyperuricemia as a result of DNA degradation secondary to massive cell death.
- Renal injury from hyperuricemia can be minimized by giving (1) fluids, (2) prophylactic allopurinol (a drug that blocks uric acid formation), and (3) if hyperuricemia develops despite these measures, rasburicase (an enzyme that catalyzes uric acid degradation).
- Anticancer drugs with vesicant properties can cause severe local injury if the IV line through which they are being administered becomes extravasated.
- Cancer chemotherapy has three possible benefits: cure, palliation, and prolongation of useful life. For treatment to be justified, at least one of these benefits should be forthcoming.

¹⁰²CHAPTER 101 Anticancer Drugs I: Cytotoxic Agents

TIMOTHY McGUIRE

RICH LEHNE

^{10...}INTRODUCTION TO THE CYTOTOXIC ANTICANCER DRUGS

The cytotoxic agents constitute the largest class of anticancer drugs. As their name implies, these agents act directly on cancer cells to cause their death. The cytotoxic drugs can be subdivided into eight major groups: (1) alkylating agents, (2) platinum compounds, (3) antimetabolites, (4) hypomethylating agents, (5) antitumor antibiotics, (6) mitotic inhibitors, (7) topoisomerase inhibitors, and (8) miscellaneous cytotoxic drugs. We do not discuss each drug in detail. Rather, we focus on selected representative agents. Individual cytotoxic agents are listed in [Table 101-1](#).

^{102.1.1}Mechanisms of Cytotoxic Action

[Table 101-2](#) summarizes the principal mechanisms by which the cytotoxic anticancer drugs act. As the table shows, most cytotoxic agents disrupt processes related to synthesis of DNA or its precursors. In addition, some agents (eg, vinblastine, vincristine) act specifically to block mitosis, and one drug—asparaginase—disrupts synthesis of proteins. Note that, with the exception of asparaginase, all of the cytotoxic drugs disrupt processes carried out exclusively by cells that are undergoing replication. As a result, these drugs are most toxic to tissues that have a high growth fraction (ie, a high proportion of proliferating cells).

^{102.1.2}Cell-Cycle Phase Specificity

As discussed in [Chapter 100](#), the cell cycle is the sequence of events that a cell goes through from one mitotic division to the next. Some anticancer agents, known as *cell-cycle phase-specific drugs*, are effective only during a specific phase of the cell cycle. Other anticancer agents, known as *cell-cycle phase-nonspecific drugs*, can affect cells during any phase of the cell cycle. About half of the cytotoxic anticancer drugs are phase specific, and the other half are phase nonspecific. The phase specificity of individual cytotoxic agents is summarized in [Table 101-1](#).

^{102.1.2.1}Cell-Cycle Phase-Specific Drugs.

Phase-specific agents are toxic only to cells that are passing through a particular phase of the cell cycle. Vincristine, for example, acts by causing mitotic arrest, and hence is effective only during M phase. Other agents act by disrupting DNA synthesis, and hence are effective only

during S phase. Because of their phase specificity, these drugs are toxic only to cells that are active participants in the cell cycle; cells that are “resting” in G_0 will not be harmed.

Obviously, if these drugs are to be effective, they must be present as neoplastic cells cycle through the specific phase in which they act. This means that these drugs must be present for an extended time. To accomplish this, phasespecific drugs are often administered by prolonged infusion. Alternatively, they can be given in multiple doses at short intervals over an extended time. Because the dosing schedule is so critical to therapeutic response, phase-specific drugs are also known as *schedule-dependent drugs*.

102.1.2.2 Cell-Cycle Phase–Nonspecific Drugs.

The phasenonspecific drugs can act during any phase of the cell cycle, including G_0 . Among the phase-nonspecific drugs are the alkylating agents and most antitumor antibiotics. Because phase-nonspecific drugs can injure cells throughout the cell cycle, whereas phase-specific drugs cannot, phasenonspecific drugs can increase cell kill when combined with phase-specific drugs.

Although the phase-nonspecific drugs can cause biochemical lesions at any time during the cell cycle, *as a rule these drugs are more toxic to proliferating cells than to cells in G_0* . There are two reasons why this is so. First, cells in G_0 have time to repair drug-induced damage before it can result in significant harm. In contrast, proliferating cells often lack time for repair. Second, toxicity may not become manifest until the cells attempt to proliferate. For example, many alkylating agents act by producing cross-links between DNA strands. Although these biochemical lesions can be made at any time, they are largely without effect until cells attempt to replicate DNA. This is much like inflicting a flat tire on an automobile: The tire can be deflated at any time; however, loss of air is consequential only if the car is moving. Carrying the analogy further, if the flat occurs while the car is stopped, and is repaired before travel is attempted, the flat will have no functional impact at all.

TABLE 101-1 Cytotoxic Anticancer Drugs

Generic Name	Trade Name	Cell-Cycle Phase Specificity	Route	Dose-Limiting Toxicity
Alkylating Agents				
Nitrogen Mustards				
Bendamustine	Treanda	Phase nonspecific	IV	Bone marrow suppression, infusion reactions
Chlorambucil	Leukeran	Phase nonspecific	PO	Bone marrow suppression
Cyclophosphamide	Cytoxan, Neosar	Phase nonspecific	PO, IV	Bone marrow suppression
Ifosfamide	Ifex	Phase nonspecific	IV	Bone marrow suppression and hemorrhagic cystitis
Mechlorethamine	Mustargen	Phase nonspecific	IV, IC, IP	Bone marrow suppression
Melphalan	Alkeran	Phase nonspecific	PO, IV	Bone marrow suppression
Nitrosoureas				
Carmustine	BiCNU, Gliadel	Phase nonspecific	IV, CNS implant	Bone marrow suppression
Lomustine	CeeNU	Phase nonspecific	PO	Bone marrow suppression
Streptozocin	Zanosar	Phase nonspecific	IV	Nephrotoxicity
Others				
Busulfan	Myleran, Busulfex	Phase nonspecific	PO, IV	Bone marrow suppression, pulmonary fibrosis
Temozolomide	Temodar	Phase nonspecific	PO	Bone marrow suppression
Platinum Compounds				
Carboplatin	Paraplatin	Phase nonspecific	IV	Bone marrow suppression
Cisplatin	Platinol-AQ	Phase nonspecific	IV	Nephrotoxicity
Oxaliplatin	Eloxatin	Phase nonspecific	IV	Peripheral neuropathy
Antimetabolites				
Folic Acid Analogs				
Methotrexate	Rheumatrex, Trexall	S-phase specific	IV, IM, PO, IT	Bone marrow suppression, mucositis
Pemetrexed	Alimta	S-phase specific	IV	Bone marrow suppression
Pyrimidine Analogs				

Pharmacology for Nursing Care, 7th Edition

Capecitabine	Xeloda	Kills dividing cells only, mainly in S phase	PO	Bone marrow suppression, diarrhea, hand-and-foot syndrome
Cytarabine	Cytosar-U, DepoCyt, Tarabine PFS	S-phase specific	IV, subQ, IT	Bone marrow suppression
Floxuridine	FUDR	Kills dividing cells only, mainly in S phase	IA	Bone marrow suppression, oral and GI ulceration
Fluorouracil	Adrucil	Kills dividing cells only, mainly in S phase	IV	Bone marrow suppression, oral and GI ulceration
Gemcitabine	Gemzar	S-phase specific	IV	Bone marrow suppression
Purine Analogs				
Cladribine	Leustatin	Kills dividing cells only, mainly in S phase	IV	Bone marrow suppression
Clofarabine	Clolar	S-phase specific	IV	Bone marrow suppression
Fludarabine	Fludara	S-phase specific	IV	Bone marrow suppression
Mercaptopurine	Purinethol	S-phase specific	PO	Bone marrow suppression
Nelarabine	Arranon	S-phase specific	IV	Neurotoxicity
Pentostatin	Nipent	S-phase specific	IV	Bone marrow suppression
Thioguanine	Tabloid	S-phase specific	PO, IV	Bone marrow suppression
Hypomethylating Agents				
Azacitidine	Vidaza	S-phase specific	subQ	Bone marrow suppression
Decitabine	Dacogen	S-phase specific	IV	Bone marrow suppression
Antitumor Antibiotics				
Anthracyclines				
Daunorubicin (liposomal)	DaunoXome	Phase nonspecific	IV	Bone marrow suppression, cardiotoxicity
Doxorubicin	Adriamycin, Doxil	Phase nonspecific	IV	Bone marrow suppression, cardiotoxicity
Epirubicin	Ellence	Phase nonspecific, but S and G ₂ most sensitive	IV	Bone marrow suppression, cardiotoxicity
Idarubicin	Idamycin	Phase nonspecific, but S most sensitive	IV	Bone marrow suppression, cardiotoxicity
Mitoxantrone*	Novantrone	Phase nonspecific	IV	Bone marrow suppression, cardiotoxicity
Nonanthracyclines				

Pharmacology for Nursing Care, 7th Edition

Bleomycin	Blenoxane	G ₂ -phase specific	IV, IM, subQ, IP	Pneumonitis and pulmonary fibrosis
Dactinomycin	Cosmegen	Phase nonspecific	IV	Bone marrow suppression, mucositis
Mitomycin	Mutamycin	Phase nonspecific, but G ₁ and S most sensitive	IV	Bone marrow suppression
Mitotic Inhibitors				
Vinca Alkaloids				
Vinblastine	Velban	M-phase specific	IV	Bone marrow suppression
Vincristine	Oncovin, Vincasar	M-phase specific	IV	Peripheral neuropathy
Vinorelbine	Navelbine	M-phase specific	IV	Bone marrow suppression
Taxanes				
Docetaxel	Taxotere	G ₂ /M-phase specific	IV	Bone marrow suppression
Paclitaxel	Abraxane, Taxol, Onxol	G ₂ /M-phase specific	IV	Bone marrow suppression
Others				
Estramustine	Emcyt	M-phase specific	PO	Nausea and vomiting
Ixabepilone	Ixempra	G ₂ /M-phase specific	IV	Bone marrow suppression, neurotoxicity
Topoisomerase Inhibitors				
Etoposide	VePesid, Toposar, Etopophos	S and G ₂ most sensitive	IV, PO	Bone marrow suppression
Irinotecan	Camptosar	S-phase specific	IV	Bone marrow suppression and late diarrhea
Teniposide	Vumon	S and G ₂ most sensitive	IV	Bone marrow suppression
Topotecan	Hycamtin	S-phase specific	IV	Bone marrow suppression
Miscellaneous				
Altretamine	Hexalen	Specificity unknown	PO	Bone marrow suppression
Asparaginase	Elspar	G ₁ -phase specific	IV, IM	None
Dacarbazine	DTIC-Dome	Phase nonspecific	IV	Bone marrow suppression
Hydroxyurea	Hydrea, Mylocel	S-phase specific	PO	Bone marrow suppression
Mitotane	Lysodren	Phase nonspecific	PO	CNS depression
Pegaspargase	Oncaspar	G ₁ -phase specific	IV, IM	None

Pharmacology for Nursing Care, 7th Edition

Procarbazine	Matulane	Phase nonspecific	PO	Bone marrow suppression
--------------	----------	-------------------	----	-------------------------

IA = intra-arterial, IC = intracavitary, IM = intramuscular, IP = intrapleural, IT = intrathecal, IV = intravenous, PO = oral, subQ = subcutaneous.

* Mitoxantrone is classified chemically as an anthracenedione, which is very similar to an anthracycline.

It should be noted that some dividing cells are more vulnerable than others. Specifically, cells that divide rapidly will be harmed more readily than cells that divide slowly. Why? Because rapidly dividing cells will have less time for repair.

102.1.3 Toxicity

As discussed in [Chapter 100](#), many anticancer drugs are toxic to normal tissues—especially tissues that have a high percentage of proliferating cells (bone marrow, hair follicles, GI epithelium, germinal epithelium). The common major toxicities of the cytotoxic anticancer drugs, together with management procedures, are discussed at length in [Chapter 100](#). Therefore, as we consider individual anticancer agents in this chapter, discussion of most toxicities is brief.

1183

1184

TABLE 101-2 Actions of Representative Cytotoxic Anticancer Drugs

Drug	Drug Action	Cellular Process Disrupted
Cyclophosphamide	Alkylates DNA, causing cross-links and strand breakage	DNA and RNA synthesis
Methotrexate	Inhibits one-carbon transfer reactions	Synthesis of DNA precursors (purines, dTMP)
Hydroxyurea	Inhibits ribonucleotide reductase	Synthesis of DNA precursors (blocks conversion of ribonucleotides into deoxyribonucleotides)
Thioguanine, mercaptopurine	Inhibits purine ring synthesis and nucleotide interconversion	Synthesis of DNA precursors (purines, pyrimidines, ribonucleotides, and deoxyribonucleotides)
Fluorouracil	Inhibits thymidylate synthetase	Synthesis of dTMP, a DNA precursor
Cytarabine	Inhibits DNA polymerase	DNA synthesis
Bleomycin	Breaks DNA strands and prevents their repair	DNA synthesis
Doxorubicin	Intercalates between base pairs of DNA and inhibits topoisomerase II	DNA and RNA synthesis
Vinblastine, vincristine	Blocks microtubule assembly	Mitosis
Asparaginase	Deaminates asparagine, depriving cells of this amino acid	Protein synthesis
Topotecan	Inhibits topoisomerase I and thereby prevents resealing of DNA strand breaks	Impairs DNA replication

^{102.1.4} Dosage, Handling, and Administration

Cancer chemotherapy is a highly specialized field. Accordingly, in a general text such as this, presentation of detailed information on dosage and administration of specific agents seems inappropriate. However, you should be aware that dosages for anticancer agents must be individualized and that timing of administration may vary with the particular protocol being followed. Also, because of the complex and hazardous nature of cancer chemotherapy, anticancer drugs should be administered under the direct supervision of a physician experienced in their use.

^{102.1.4.1} Handling of Cytotoxic Drugs.

Antineoplastic drugs are often mutagenic, teratogenic, and carcinogenic. In addition, direct contact with the skin, eyes, and mucous membranes can result in local injury (and can increase

cancer risk if enough drug is absorbed). Accordingly, it is imperative that healthcare personnel involved in the preparation and administration of these drugs follow safe handling procedures. Risk of injury from contact with parenteral chemotherapeutic drugs can be minimized by using biologic safety cabinets and by following approved procedures for compounding and administration.

102.1.4.2 Administration of Vesicants.

As discussed in [Chapter 100](#), extravasation of vesicants can cause severe local injury, sometimes requiring surgical débridement and skin grafting. Drugs with strong vesicant properties include carmustine, dacarbazine, dactinomycin, daunorubicin, doxorubicin, mechlorethamine, mitomycin, plicamycin, streptozocin, vinblastine, and vincristine. To minimize the risk of injury, IV administration should be performed only into a vein with good flow. Sites of previous irradiation should be avoided. If extravasation occurs, the infusion should be discontinued immediately.

10... ALKYLATING AGENTS

The family of alkylating agents consists of nitrogen mustards, nitrosoureas, and other compounds. Before considering the properties of individual alkylating agents, we discuss the characteristics of the group as a whole. The alkylating agents are listed in [Table 101-1](#).

102.2.1 Shared Properties

102.2.1.1 Mechanism of Action.

The alkylating agents are highly reactive compounds that have the ability to transfer an alkyl group to a variety of cell constituents. Cell kill results primarily from alkylation of DNA. As a rule, alkylating agents interact with DNA by forming a covalent bond with a specific nitrogen atom in guanine ([Fig. 101-1](#)).

Some alkylating agents have two reactive sites, whereas others have only one. Alkylating agents with two reactive sites (*bifunctional* agents) are able to bind DNA in two places to form *cross-links*. These bridges may be formed within a single strand of DNA or between parallel DNA strands. [Figure 101-1](#) illustrates the production of interstrand cross-links by nitrogen mustard. Alkylating agents with only one reactive site (*monofunctional* agents) lack the ability to form cross-links, but can still bind to a single guanine in DNA.

1184

Figure 101-1 Cross-linking of DNA by an alkylating agent. **A** Reactions leading to cross-linkage between guanine moieties in DNA. **B**, Schematic representation of interstrand cross-linking within the DNA double helix. (A = adenine, C = cytosine, G = guanine, T = thymine.)

The consequences of guanine alkylation are miscoding, scission of DNA strands, and, if cross-links have been formed, inhibition of DNA replication. Because cross-linking of DNA is especially injurious, cell death is more likely with bifunctional agents than with monofunctional agents.

Because alkylation reactions can take place at any time during the cell cycle, alkylating agents are considered *cell-cycle phase nonspecific*. However, *most of these drugs are more toxic to dividing cells—especially cells that divide rapidly—than they are to cells in G₀*. Why? Because (1) alkylation of DNA produces its most detrimental effects when cells attempt to replicate DNA, and (2) resting cells are often able to repair damage to DNA before it can affect cell function. Because alkylating agents are phase nonspecific, they needn't be present over an extended time. Accordingly, they can be administered by bolus dosing, rather than by prolonged infusion.

102.2.1.2 Resistance.

Development of resistance to alkylating agents is common. A major cause is increased production of enzymes that repair DNA. Resistance may also result from decreased uptake of alkylating agents and from increased production of nucleophiles (compounds that act as decoy targets for alkylation).

102.2.1.3 Toxicities.

Alkylating agents are toxic to tissues that have a high growth fraction. Accordingly, these drugs may injure cells of the bone marrow, hair follicles, GI mucosa, and germinal epithelium. Blood dyscrasias—neutropenia, thrombocytopenia, and anemia—caused by bone marrow suppression are of greatest concern. Nausea and vomiting occur with all alkylating agents. Also, several of these drugs are vesicants, and hence must be administered through a free-flowing IV line.

1185

1186

102.2.2 Properties of Individual Alkylating Agents

102.2.2.1 Nitrogen Mustards

102.2.2.1.1 Cyclophosphamide.

Cyclophosphamide [Cytosan, Neosar] is a bifunctional alkylating agent active against a *broad spectrum* of neoplastic diseases. Indications include *Hodgkin's disease, non-Hodgkin's lymphomas, multiple myeloma, and solid tumors of the head, neck, ovary, and breast*. Of all the alkylating agents, cyclophosphamide is employed most widely.

Cyclophosphamide is a prodrug that undergoes conversion to its active form in the liver. Because activation is required, onset of effects is delayed. Cyclophosphamide is not a vesicant, and hence can be administered PO as well as IV. Oral doses should be administered with food.

The major dose-limiting toxicity is bone marrow suppression. Severe nausea, vomiting, and alopecia are also common, especially at high doses. In addition, the drug can cause acute hemorrhagic cystitis; bladder injury and associated bleeding can be minimized by (1) maintaining adequate hydration, and (2) giving a protective agent called *mesna* [Mesnex] when high-dose cyclophosphamide is employed. Other adverse effects include sterility, immunosuppression, and hypersensitivity reactions.

102.2.2.1.2 Mechlorethamine.

Mechlorethamine [Mustargen], a bifunctional compound, was the first alkylating agent employed clinically. Indications include *bronchogenic carcinoma*, *Hodgkin's disease*, *leukemias*, and *mycosis fungoides*. Mechlorethamine is a powerful vesicant and can cause severe local injury. Accordingly, for systemic therapy, the drug must be administered IV. Caution must be exercised to avoid both extravasation and direct contact with the skin. Once in the bloodstream, mechlorethamine undergoes rapid conversion to active metabolites. The dose-limiting toxicity is bone marrow suppression. Other major toxicities include severe nausea and vomiting, alopecia, diarrhea, stomatitis, amenorrhea, and sterility.

102.2.2.1.3 Bendamustine.

Bendamustine [Treanda], approved in 2008, is a derivative of mechlorethamine, and may be better tolerated. The drug has only one indication: *chronic lymphocytic leukemia*. Administration is IV. As with mechlorethamine, the dose-limiting toxicity is bone marrow suppression. Nausea and vomiting are common. Some patients experience an infusion reaction, characterized by fever, hypotension, chills, rigors, and myalgias. Fluvoxamine [Luvox] and other drugs that inhibit CYP1A2 (the 1A2 isozyme of cytochrome P450) may raise bendamustine levels, whereas carbamazepine [Tegretol] and other drugs that induce CYP1A2 may reduce bendamustine levels.

102.2.2.1.4 Chlorambucil.

Chlorambucil [Leukeran], an oral nitrogen mustard, is generally well tolerated. Bone marrow suppression is the major dose-limiting toxicity. Other adverse effects include hepatotoxicity, sterility, and rare pulmonary fibrosis. Nausea and vomiting are usually mild. Chlorambucil is a drug of choice for palliative therapy of *chronic lymphocytic leukemia*. The drug is also used for *Hodgkin's disease*, *non-Hodgkin's lymphomas*, and *multiple myeloma*.

102.2.2.1.5 Melphalan.

Melphalan [Alkeran], a bifunctional agent, is generally well tolerated. Bone marrow suppression is the major dose-limiting toxicity. The drug can cause secondary malignancy and is mutagenic like other alkylating agents. Melphalan is not a vesicant. Severe nausea and vomiting are rare. Administration is PO and IV. Melphalan is a preferred drug for *multiple myeloma*, and is also active against *lymphoma* and *carcinoma of the ovary and breast*.

102.2.2.1.6 Ifosfamide.

Ifosfamide [Ifex], a derivative of cyclophosphamide, is approved for refractory *germ cell testicular cancer*, and is used off-label against many other tumors, including *Hodgkin's and non-Hodgkin's lymphomas*, *non-small cell and small cell lung cancer*, and *head and neck cancer*. Dose-limiting toxicities are bone marrow suppression and hemorrhagic cystitis. The risk of cystitis is minimized by concurrent therapy with *mesna* [Mesnex] and by extensive hydration (at least 2 L of oral or IV fluid daily). Owing to the risk of cystitis, urinalysis should be performed before each dose. If the analysis reveals microscopic hematuria, dosing should be postponed until the hematuria resolves. Additional adverse effects include nausea, vomiting, metabolic acidosis, and central nervous system (CNS) toxicity (confusion, hallucinations, blurred vision, coma). Severe adverse effects are most likely in patients receiving high-dose therapy and in those with renal failure. Administration is IV.

102.2.2.2 Nitrosoureas

The nitrosoureas are bifunctional alkylating agents, and are active against a broad spectrum of neoplastic diseases. Cell kill results from cross-linking DNA. Unlike many anticancer drugs, the nitrosoureas are highly lipophilic, and hence can readily penetrate the blood-brain barrier. As a result, these drugs are especially useful against *cancers of the CNS*. The major dose-limiting toxicity is *delayed bone marrow suppression*.

102.2.2.2.1 Carmustine (BCNU).

Carmustine [BiCNU, Gliadel] was the first nitrosourea to undergo extensive clinical testing and can be considered the prototype for the group. Because of its ability to cross the blood-brain barrier, carmustine is especially useful against *primary and metastatic tumors of the brain*. Other indications include *Hodgkin's disease*, *non-Hodgkin's lymphomas*, *multiple myeloma*, *malignant melanoma*, *hepatoma*, and *adenocarcinoma of the stomach, colon, and rectum*. The principal dose-limiting toxicity is delayed bone marrow suppression; leukocyte and platelet nadirs occur 4 to 6 weeks after treatment. Nausea and vomiting can be severe.

Injury to the liver and kidneys has been reported. High cumulative doses may cause pulmonary fibrosis. Accordingly, if pulmonary function begins to decline, corticosteroids should be given to prevent fibrosis.

Administration may be topical or IV. Topical administration is done by implanting a biodegradable, carmustine-impregnated wafer [Gliadel] into the cavity created by surgical removal of a brain tumor. This technique has the obvious benefit of concentrating the drug where it is most needed. When administered IV, carmustine can cause local phlebitis and extravasation injury, even though it is not a vesicant.

102.2.2.2.2 Lomustine (CCNU).

Lomustine [CeeNU] is similar to carmustine in actions and uses. Like carmustine, lomustine crosses the blood-brain barrier and is approved for *brain cancer*. The drug is also approved for *Hodgkin's disease*. As with carmustine, the major dose-limiting toxicity is delayed bone marrow suppression. Additional toxicities include nausea and vomiting, renal and hepatic toxicity, pulmonary fibrosis, and neurologic reactions. Administration is oral.

102.2.2.2.3 Streptozocin.

Streptozocin [Zanosar] differs significantly from other nitrosoureas. The drug contains a glucose moiety that causes selective uptake by islet cells of the pancreas. This property underlies the drug's only approved indication: *metastatic islet cell tumors*. The major dose-limiting toxicity is kidney damage. Accordingly, renal function should be monitored in all patients. Nausea and vomiting can be severe. Additional toxicities include hypoglycemia, hyperglycemia, diarrhea, chills, and fever. In contrast to other nitrosoureas, streptozocin causes minimal bone marrow suppression. Administration is IV.

102.2.2.3 Other Alkylating Agents

102.2.2.3.1 Busulfan.

Busulfan [Myleran, Busulfex] is a bifunctional agent with only one approved indication: *chronic myelogenous leukemia*. Dose-limiting toxicities are bone marrow suppression, pulmonary infiltrates, and pulmonary fibrosis. Other toxicities include nausea, vomiting, alopecia, gynecomastia, male and female sterility, skin hyperpigmentation, cataracts, seizures, and liver injury. Administration is oral and IV.

102.2.2.3.2 Temozolomide.

102.2.2.3.2.1 Therapeutic Uses.

Temozolomide [Temodar], approved in 1999, is indicated for oral therapy of adults with *anaplastic astrocytoma* that has relapsed after treatment with preferred agents: procarbazine and a nitrosourea (lomustine or carmustine). Temozolomide can also benefit patients with recurrent *glioblastoma multiforme*. Both of these cancers arise from glial cells in the brain, and both eventually recur despite aggressive treatment. However, even though temozolomide cannot offer cure, it can increase health-related quality of life. The initial dosage is 150 mg/m² once daily for 5 consecutive days, repeated every 28 days. In clinical trials, temozolomide produced partial tumor shrinkage in 27% of patients, and complete shrinkage in 8%.

1186

1187

102.2.2.3.2.2 Pharmacokinetics and Mechanism of Action.

Temozolomide undergoes nearly complete absorption following oral dosing. Food reduces both the rate and extent of absorption. Once in the body, temozolomide undergoes rapid, nonenzymatic conversion to its active form, an alkylating agent known as MTIC. As MTIC, the drug alkylates DNA, and thereby causes cell death. Temozolomide readily crosses the blood-brain barrier to reach its site of action. The elimination half-life is 1.8 hours.

102.2.2.3.2.3 Adverse Effects.

The major dose-limiting toxicity is myelosuppression, manifesting as neutropenia and thrombocytopenia. The most common adverse effects are nausea (53%) and vomiting (42%). Both respond well to antiemetic drugs. Other common reactions include headache (41%), fatigue (34%), constipation (33%), and diarrhea (16%). Convulsions may also occur. Patients must not open temozolomide capsules; the drug can cause local injury following inhalation or contact with the skin or mucous membranes.

^{10...} PLATINUM COMPOUNDS

The platinum-containing anticancer drugs—cisplatin, carboplatin, and oxaliplatin—are very similar to the alkylating agents, and are often classified as such. Like the bifunctional alkylating agents, the platinum compounds produce cross-links in DNA, and hence are cell-cycle phase nonspecific.

102.3.1 Cisplatin

Cisplatin [Platinol-AQ] kills cells primarily by forming cross-links between and within strands of DNA. The drug is approved only for *metastatic testicular and ovarian cancers* and *advanced bladder cancer*. Nonetheless, it is used off-label as a component in standard-of-care regimens for *lung cancer* and *head and neck cancer*. The major dose-limiting toxicity is kidney damage, which can be minimized by extensive hydration coupled with diuretic therapy and *amifostine* [Ethyol]. Cisplatin is highly emetogenic; nausea and vomiting begin about 1 hour after administration and can persist for several days after dosing. Other adverse effects include clinically important peripheral neuropathy, mild to moderate bone marrow suppression, and ototoxicity, which manifests as tinnitus and high-frequency hearing loss. Administration is by IV infusion.

102.3.2 Carboplatin

Carboplatin [Paraplatin] is an analog of cisplatin. Cell kill appears to result from cross-linking DNA. The drug's only approved indications are initial and palliative therapy of advanced *ovarian cancer*. Unlabeled uses include *small cell cancer of the lung*, *squamous cell cancer of the head and neck*, and *endometrial cancer*. The major dose-limiting toxicity is bone marrow suppression. Nausea and vomiting occur, but are less severe than with cisplatin. Similarly, nephrotoxicity, neurotoxicity, and hearing loss are less frequent than with cisplatin. Carboplatin is administered by IV infusion. Anaphylactic reactions have occurred minutes after administration; symptoms can be managed with epinephrine, glucocorticoids, and antihistamines.

102.3.3 Oxaliplatin

102.3.3.1 Actions and Uses.

Oxaliplatin [Eloxatin], approved in 2002, is similar to carboplatin. Like carboplatin, oxaliplatin produces intra- and interstrand cross-links in DNA. Currently, oxaliplatin is approved only for *colorectal cancer*, and only in combination with fluorouracil/leucovorin (leucovorin potentiates the activity of fluorouracil). This regimen may be used for adjuvant therapy following complete tumor resection, or in patients with advanced colorectal cancer. Investigational uses include *mesothelioma*, *non-Hodgkin's lymphoma*, and *cancers of the breast, ovary, pancreas, prostate, and lung*. Administration is by IV infusion.

102.3.3.2 Toxicity.

102.3.3.2.1 Peripheral Sensory Neuropathy.

The major dose-limiting toxicity is peripheral sensory neuropathy, manifesting as numbness or tingling in the fingers and toes and around the mouth and throat. Neuropathy develops in most patients, either early in treatment or after several courses. Neuropathy may impede activities of daily living, such as buttoning clothing, writing, or just holding things. Symptoms are often intensified by exposure to cold. Accordingly, patients should be warned to cover exposed skin before touching cold objects or entering a cold environment. Also, patients should avoid cold liquids and use of ice. Oxaliplatin-induced neuropathy typically resolves after treatment stops, although complete recovery may take several months. Oral gabapentin may reduce or prevent neuropathy.

102.3.3.2.2 Other Toxicities.

Damage to bone marrow can cause anemia (64%), neutropenia (15% with oxaliplatin alone, 66% when combined with fluorouracil), and thrombocytopenia (41% with oxaliplatin alone, 76% when combined with fluorouracil). Other common reactions are nausea and vomiting (70%), liver abnormalities (46%), diarrhea (41%), fever (36%), abdominal pain (31%), and infection (23%). Alopecia occurs in 2% of patients. Life-threatening anaphylactoid reactions may develop, but are uncommon; epinephrine, glucocorticoids, and antihistamines have been employed for treatment.

^{10...} ANTIMETABOLITES

Antimetabolites are structural analogs of important natural metabolites. Because they resemble natural metabolites, these drugs are able to disrupt critical metabolic processes. Some antimetabolites inhibit enzymes that synthesize essential cellular constituents. Others undergo incorporation into DNA, and thereby disrupt DNA replication and function.

Antimetabolites are effective only against cells that are active participants in the cell cycle. Most antimetabolites are S-phase specific, although some can act during any phase of the cycle, except G₀. To be effective, agents that are S-phase specific must be present for an extended time.

There are three classes of antimetabolites: (1) folic acid analogs, (2) pyrimidine analogs, and (3) purine analogs. Members of each class are listed in [Table 101-1](#).

102.4.1 Folic Acid Analogs

Folic acid, in its active form, is needed for several essential biochemical reactions. The folic acid analogs act by blocking the conversion of folic acid to its active form. At this time, two analogs of folic acid are used against cancer: methotrexate and pemetrexed. Other folate analogs are used to treat bacterial infections (trimethoprim), malaria (pyrimethamine), and *Pneumocystis jiroveci* pneumonia (trimetrexate).

102.4.1.1 Methotrexate

102.4.1.1.1 Mechanism of Action.

As shown in [Figure 101-2](#), methotrexate [Rheumatrex, Trexall] *inhibits dihydrofolate reductase*, the enzyme that converts dihydrofolic acid (FH₂) into tetrahydrofolic acid (FH₄). Since production of FH₄ is a necessary step in the activation of folic acid, and since activated folic acid is required for biosynthesis of essential cellular constituents (DNA, RNA, proteins), inhibition of FH₄ production has multiple effects on the cell. Of all the processes that are suppressed by reduced FH₄ availability, biosynthesis of thymidylate appears most critical. Why? Because, in the absence of thymidylate, cells are unable to make DNA. Because cell kill results primarily from disrupting DNA synthesis, methotrexate is considered *S-phase specific*. Please note, however, that in addition to this S-phase effect, methotrexate has another beneficial action: the fall in thymidine levels caused by methotrexate is a potent signal for inducing apoptosis (programmed cell death).

1187

1188

Figure 101-2 Actions of methotrexate, leucovorin, and fluorouracil. (FdUMP = 5-fluoro-2'-deoxyuridine-5'-monophosphate, X = blockade of reaction.)

A technique known as *leucovorin rescue* can be employed to enhance the effects of methotrexate. Some neoplastic cells are unresponsive to methotrexate because they lack the transport system required for active uptake of the drug. By giving massive doses of methotrexate, we can force the drug into these cells by passive diffusion. However, because this process also exposes normal cells to extremely high concentrations of methotrexate, normal cells are also at risk. To save them, leucovorin (citrovorum factor, folinic acid) is given. As shown in [Figure 101-2](#), leucovorin bypasses the metabolic block caused by methotrexate, thereby permitting normal cells to synthesize thymidylate and other compounds. Malignant cells are not saved to the same extent because leucovorin uptake requires the same transport system employed for methotrexate uptake, a transport system these cells lack. It should be noted that leucovorin rescue is potentially dangerous: *Failure to administer leucovorin in the right dose at the right time can be fatal.*

102.4.1.1.2 Pharmacokinetics.

Methotrexate can be administered PO, IM, IV, and intrathecally. The drug is highly polar, and hence a transport system is needed to enter mammalian cells. In cancer cells and normal cells, methotrexate undergoes enzymatic activation to a polyglutamated form. Elimination is primarily renal. Hence, in patients with renal impairment, dosage must be reduced to prevent the drug from accumulating to toxic levels.

Because methotrexate is highly polar, it crosses the blood-brain barrier poorly, except when given in very high doses. To ensure effective levels, intrathecal administration is employed for most CNS cancers.

102.4.1.1.3 Resistance.

Cancer cells can acquire resistance to methotrexate via five mechanisms: (1) decreased uptake of methotrexate, (2) increased synthesis of dihydrofolate reductase (the target enzyme for methotrexate), (3) synthesis of a modified form of dihydrofolate reductase that has a reduced affinity for methotrexate, (4) increased production of a transporter that pumps methotrexate out of cells, and (5) reduced production of enzymes needed to convert methotrexate to its active (polyglutamated) form.

102.4.1.1.4 Therapeutic Uses.

Methotrexate is curative for women with *choriocarcinoma*. The drug is also active against *non-Hodgkin's lymphomas* and *acute lymphocytic leukemia of childhood*. Very large doses coupled with leucovorin rescue have been employed to treat *head and neck sarcomas* and

osteogenic sarcoma. Noncancer applications include *rheumatoid arthritis* ([Chapter 72](#)), *Crohn's disease* ([Chapter 79](#)), *psoriasis* ([Chapter 104](#)), and *abortion* ([Chapter 61](#)).

102.4.1.1.5 Toxicity.

The usual dose-limiting toxicities are bone marrow suppression, pulmonary infiltrates and fibrosis, and oral and GI ulceration. Death may result from intestinal perforation and hemorrhagic enteritis. Nausea and vomiting may occur shortly after administration. High doses can directly injure the kidneys. To promote drug excretion, and thereby minimize renal damage, the urine should be alkalinized and adequate hydration should be maintained. Methotrexate has been associated with fetal malformation and death. Accordingly, pregnancy should be avoided until at least 6 months after completing treatment.

102.4.1.2 Pemetrexed

102.4.1.2.1 Mechanism of Action.

Pemetrexed [Alimta], approved in 2004, is an antifolate compound with actions similar to those of methotrexate. Like methotrexate, pemetrexed inhibits dihydrofolate reductase. However, unlike methotrexate, pemetrexed also inhibits two other enzymes: thymidylate synthase and glycinamide ribonucleotide formyltransferase. All three enzymes are involved in the *de novo* synthesis of thymidine and purine nucleotides. By inhibiting these enzymes, pemetrexed can suppress synthesis of DNA, RNA, and proteins. Cell death results primarily from disrupting DNA synthesis and function. Pemetrexed is considered S-phase specific.

102.4.1.2.2 Therapeutic Uses.

Pemetrexed, in combination with cisplatin, is approved for IV therapy of unresectable *malignant pleural mesothelioma*, a rare cancer usually associated with asbestos exposure. The drug is also approved for monotherapy of *non-small cell lung cancer* following prior chemotherapy. Investigational uses include *gastric, pancreatic, and breast cancer*.

1188

102.4.1.2.3 Pharmacokinetics.

1189

Pemetrexed is administered IV and, like methotrexate, undergoes conversion to active polyglutamates within cells. (Compared with normal cells, cancer cells are more efficient at polyglutamation, and hence cancer cells are more likely to be harmed.) Pemetrexed is eliminated by renal excretion. In patients with normal renal function, the elimination half-life is 3.5 hours. In patients with renal impairment, elimination is delayed.

102.4.1.2.4 Toxicity.

The most common adverse effects are bone marrow suppression (the usual dose-limiting toxicity), GI disturbances (nausea, diarrhea, and sores of the lips, mouth, and throat), skin rash, and fatigue. To reduce bone marrow and GI toxicity, patients should receive prophylactic doses of vitamin B₁₂ and folic acid, starting a week prior to dosing. To reduce skin rash, patients should receive prophylactic glucocorticoids (eg, dexamethasone). Pemetrexed can cause fetal malformation and death, and hence should not be used during pregnancy. The drug is not a vesicant, and hence extravasation is managed as it would be for other nonvesicants.

102.4.2 Pyrimidine Analogs

Pyrimidines—cytosine, thymine, and uracil—are bases employed in the biosynthesis of DNA and RNA. The pyrimidine analogs, because of their structural similarity to naturally occurring pyrimidines, can act in several ways: (1) they can inhibit biosynthesis of pyrimidines, (2) they can inhibit biosynthesis of DNA and RNA, and (3) they can undergo incorporation into DNA and RNA, and thereby disrupt nucleic acid function. All of the pyrimidine analogs are prodrugs that must be converted to their active forms in the body.

102.4.2.1 Cytarabine

Cytarabine, also known as *cytosine arabinoside* and *Ara-C*, is an analog of deoxycytidine. The drug has an established role in treating *acute myelogenous leukemia*. Cytarabine is available in two formulations: (1) conventional [Cytosar-U, Tarabine PFS], for IV and subQ administration, and (2) liposomal [DepoCyt], for intrathecal administration.

102.4.2.1.1 Mechanism of Action.

Cytarabine is converted to its active form—Ara-CTP—within the body. As Ara-CTP, the drug undergoes incorporation into DNA. By a mechanism that is not fully understood, incorporation suppresses further DNA synthesis. Ara-CTP may also impede DNA synthesis by a second mechanism: inhibition of DNA polymerase. Cytarabine is S-phase specific.

102.4.2.1.2 Resistance.

Decreased conversion of cytarabine to Ara-CTP is a major cause of resistance. Other mechanisms include decreased uptake of cytarabine, increased conversion of cytarabine to an inactive product, and increased production of dCTP (the natural metabolite that Ara-CTP competes with for incorporation into DNA).

102.4.2.1.3 Pharmacokinetics.

Administration may be IV, subQ, or intrathecal. Cytarabine is not active orally. Drug that is not taken up by cells undergoes rapid deamination in the liver. Metabolites are excreted in the urine.

102.4.2.1.4 Therapeutic Uses.

The principal indication for cytarabine is *acute myelogenous leukemia*. To induce remission, the drug is combined with idarubicin as part of the so-called 7 + 3 regimen (7 days of cytarabine + 3 days of idarubicin). Other applications include *acute lymphocytic leukemia*, *non-Hodgkin's lymphomas*, and *lymphomatous meningitis*.

102.4.2.1.5 Toxicity.

Bone marrow suppression (neutropenia, thrombocytopenia) is the usual dose-limiting toxicity. Nausea, vomiting, and fever may develop, especially after bolus IV injection. Other toxicities include stomatitis, liver injury, and conjunctivitis. High doses may cause pulmonary edema and cerebellar toxicity.

The liposomal formulation can cause chemical arachnoiditis, manifesting as nausea, vomiting, headache, and fever. Left untreated, the condition can be fatal. The incidence and severity of the reaction can be reduced by coadministration of dexamethasone, an anti-inflammatory glucocorticoid.

102.4.2.2 Fluorouracil

Fluorouracil [Adrucil] is a fluorinated derivative of uracil. The drug is employed extensively to treat solid tumors.

102.4.2.2.1 Mechanism of Action.

In order to exert cytotoxic effects, fluorouracil must be converted to its active form, 5-fluoro-2'-deoxyuridine-5'-monophosphate (FdUMP). As shown in [Figure 101-2](#), FdUMP inhibits thymidylate synthetase, thereby depriving cells of thymidylate needed to make DNA. Fluorouracil is active only against cells that are going through the cell cycle, and shows some S-phase specificity.

102.4.2.2.2 Resistance.

Potential mechanisms for resistance are (1) decreased activation of fluorouracil and (2) production of altered thymidylate synthetase that has a low affinity for FdUMP. The clinical significance of these mechanisms has not been established.

102.4.2.2.3 Therapeutic Uses.

Chemotherapeutic use of fluorouracil is limited to solid tumors. The drug is employed, together with other drugs, in the adjuvant treatment of *breast and colorectal cancer*, and in palliative therapy of *carcinomas of the colon, rectum, breast, stomach, and pancreas*. As discussed in [Chapter 104](#), fluorouracil can be used topically to treat *premalignant keratoses*.

102.4.2.2.4 Pharmacokinetics.

Administration is IV. Continuous infusion is more effective and less toxic than bolus administration. Fluorouracil is distributed widely and enters the CNS with ease. Elimination is by rapid hepatic metabolism.

102.4.2.2.5 Toxicity.

The usual dose-limiting toxicities are bone marrow suppression (neutropenia) and oral and GI ulceration. To minimize GI injury (eg, ulceration of the oropharynx or bowel), fluorouracil should be discontinued as soon as mild reactions (stomatitis, diarrhea) occur. Dosage can also be limited by palmar-plantar erythrodysesthesia (hand-and-foot syndrome), characterized by tingling, burning, redness, flaking, swelling, and blistering of the palms and soles. Other adverse effects include alopecia, hyperpigmentation, and neurologic deficits.

102.4.2.3 Capecitabine

Capecitabine [Xeloda], a prodrug form of fluorouracil, is indicated for oral therapy of metastatic *breast cancer* as well as *colorectal cancer* in both the adjuvant and metastatic settings. Once in the body, capecitabine undergoes metabolic conversion to fluorouracil and then to FdUMP, its active form. Consequently, the pharmacology of capecitabine is much like that of fluorouracil itself. Cell kill results from inhibition of thymidylate synthetase. Capecitabine is active only against dividing cells, and like fluorouracil, shows some S-phase specificity. In clinical trials, 20% of patients with breast cancer experienced at least a 50% decrease in tumor size. Severe diarrhea is common and can be dose limiting. Other common side effects include nausea, vomiting, stomatitis, and hand-and-foot syndrome, characterized by local tingling, numbness, pain, swelling, and erythema of the palms and soles. Capecitabine

is a teratogen and hence must not be used during pregnancy. The drug can cause leukopenia, but severe myelosuppression is uncommon. Alopecia has not been reported. Postmarketing surveillance has shown that capecitabine enhances the effects of warfarin; to reduce the risk of bleeding, anticoagulant effects should be monitored closely, and warfarin dosage reduced if indicated. The recommended dosage for capecitabine is 1250 mg/m^2 taken twice daily (after eating) for 14 days, followed by 7 days off. This pattern is repeated as appropriate. In patients with renal impairment, capecitabine can accumulate to toxic levels. If renal impairment is *moderate*, dosage should be reduced by 75%; if impairment is *severe*, the drug should not be used.

102.4.2.4 Floxuridine

Floxuridine [FUDR], like fluorouracil, is converted to FdUMP in the body. Hence, the pharmacologic effects of floxuridine and fluorouracil are nearly identical. Floxuridine is indicated only for *GI adenoma metastatic to the liver*. For this cancer, the drug is administered by infusion directly into the hepatic artery. The major dose-limiting toxicities are bone marrow suppression and oral and GI ulceration.

102.4.2.5 Gemcitabine

102.4.2.5.1 Mechanism of Action.

Gemcitabine [Gemzar] is a nucleoside analog that inhibits DNA synthesis. Hence, the drug is S-phase specific. Following uptake by cells, gemcitabine is converted to two active forms: gemcitabine diphosphate and gemcitabine triphosphate. Gemcitabine diphosphate inhibits ribonucleotide reductase, an enzyme needed to form deoxynucleoside triphosphates, which are required for DNA synthesis. Gemcitabine triphosphate undergoes incorporation into DNA, where it inhibits further strand elongation.

102.4.2.5.2 Therapeutic Uses

Gemcitabine is indicated for *adenocarcinoma of the pancreas* and *non-small cell cancer of the lung*. For pancreatic cancer, the drug may be used as first-line therapy in patients with locally advanced or metastatic disease, and in patients previously treated with fluorouracil. In clinical trials, gemcitabine reduced pain, improved functional status, and prolonged life slightly. The recommended dosage is 1000 mg/m^2 infused IV over 30 minutes once a week for up to 7 weeks. After a 1-week hiatus, treatment is resumed, but dosing is reduced to one infusion every 3 to 4 weeks.

102.4.2.5.3 Toxicity.

Although gemcitabine can cause a wide variety of adverse effects, it is fairly well tolerated. Myelosuppression is dose limiting. Nausea and vomiting are common (70%) but usually mild to moderate. Other common reactions include elevation of serum transaminases (75%), proteinuria (45%), hematuria (35%), pain (45%), fever (41%), rash (30%), and a flu-like syndrome (19%). Less common reactions include diarrhea, constipation, stomatitis, dyspnea, paresthesias, edema, and alopecia. Infusion reactions (eg, hypotension, flushing) may occur, and can be managed by slowing the infusion rate.

102.4.3 Purine Analogs

Like the pyrimidines, the purines—adenine, guanine, and hypoxanthine—are bases employed for biosynthesis of nucleic acids. The purine analogs discussed in this chapter are used primarily in the treatment of cancer. Purine analogs discussed in other chapters are used for immunosuppression, antiviral therapy, and gout.

102.4.3.1 Mercaptopurine

102.4.3.1.1 Mechanisms of Action and Resistance.

Mercapto-purine [Purinethol] is a prodrug that undergoes conversion to its active form within cells. Following activation, the drug can disrupt multiple biochemical processes, including purine biosynthesis, nucleotide interconversion, and biosynthesis of nucleic acids. All of these actions probably contribute to cytotoxic effects. Mercaptopurine is S-phase specific. Mechanisms of resistance include reduced activation of the drug and accelerated deactivation.

102.4.3.1.2 Pharmacokinetics.

Mercaptopurine is administered orally and undergoes erratic absorption. Absorbed drug is distributed widely, but not to the CNS. Extensive metabolism occurs in the liver; an important reaction is catalyzed by xanthine oxidase. Accordingly, for patients receiving allopurinol (an inhibitor of xanthine oxidase), mercaptopurine dosage should be reduced.

102.4.3.1.3 Therapeutic Uses.

The principal indication for mercaptopurine is maintenance therapy of *acute lymphocytic leukemia* in children and adults.

102.4.3.1.4 Toxicity.

Bone marrow suppression (neutropenia, thrombocytopenia, anemia) is the principal dose-limiting toxicity. Mild hepatotoxicity, manifesting as elevations in bilirubin and liver transaminases, is relatively common; rarely, hepatic injury has progressed to fatal liver failure. Other adverse effects include nausea, vomiting, and oral and intestinal ulceration. Concurrent use of allopurinol increases the overall toxicity risk. Mercaptopurine is mutagenic, and hence must not be used during pregnancy.

102.4.3.2 Thioguanine

102.4.3.2.1 Actions and Uses.

Thioguanine [Tabloid] acts much like mercapto-purine. Following conversion to its active form, thioguanine inhibits purine synthesis and the interconversion of nucleotides. DNA synthesis is also inhibited. Like mercaptopurine, thioguanine is S-phase specific. The drug is used primarily for *acute nonlymphocytic leukemias*.

102.4.3.2.2 Pharmacokinetics.

Administration is oral. Absorption is erratic and incomplete. Thioguanine does not distribute to the CNS. Inactivation is by hepatic metabolism. In contrast to mercaptopurine, thioguanine is not degraded by xanthine oxidase, and hence can be employed concurrently with allopurinol without a dosage reduction.

102.4.3.2.3 Toxicity.

The usual dose-limiting toxicity is bone marrow suppression. Gastrointestinal reactions (nausea, vomiting, diarrhea) may develop, but these are less severe than with mercaptopurine. Liver injury, manifesting as cholestatic jaundice, may occur.

102.4.3.3 Pentostatin

Pentostatin [Nipent] is an analog of adenosine. The drug acts in two major ways. First, it inhibits adenosine deaminase, causing accumulation of adeno-sine and deoxyadenosine nucleotides, compounds that inhibit ribonucleotide reductase and thereby block DNA synthesis. Second, pentostatin promotes accumulation of S-adenosyl homocysteine, a compound that is especially toxic to lymphocytes. The drug has only one approved indication: *hairy cell leukemia* that has not responded to interferon alfa. The major dose-limiting toxicities are bone marrow suppression and CNS depression. Other toxicities include nausea, vomiting,

rash, and fever. Combined use with fludarabine has caused fatal pulmonary toxicity, and hence is not recommended. Administration is by IV bolus or IV infusion.

102.4.3.4 Fludarabine

Fludarabine [Fludara] is an analog of adenosine. The drug is used primarily for *chronic lymphocytic leukemia*, *low-grade non-Hodgkin's lymphoma*, and *acute myelogenous leukemia*. Administration is IV or PO. Once in the body, fludarabine undergoes rapid conversion to its active form, 2-fluoro-ara-ATP. Cell kill appears to result from several mechanisms, including inhibition of DNA replication, impairment of RNA function, and promotion of apoptosis. Thus the drug is probably S-phase specific. The major dose-limiting toxicity is bone marrow suppression (neutropenia, thrombocytopenia, anemia). Other common toxicities include nausea, vomiting, and chills. Life-threatening autoimmune hemolytic anemia has been reported. When given in especially high doses, fludarabine can cause severe neurologic effects, including blindness, coma, and death. However, neurologic effects are rare (0.2%) at maximal recommended therapeutic doses. Combined use with pentostatin has been associated with fatal pulmonary toxicity, and hence is not recommended.

102.4.3.5 Cladribine

Cladribine [Leustatin] is an adenosine analog with a unique combination of actions. Unlike other purine analogs, which inhibit DNA synthesis only, cladribine inhibits both DNA synthesis and repair. As a result, the drug is active against quiescent cells as well as cells that are actively dividing. Cladribine is highly active against *hairy cell leukemia* and is considered a drug of choice for this cancer. The drug is also active against *chronic lymphocytic leukemia*, *low-grade non-Hodgkin's lymphomas*, *acute myeloid leukemia*, and *mycosis fungoides*. The major dose-limiting toxicity is myelosuppression. Very high doses (4 to 9 times normal) have caused acute nephrotoxicity and delayed-onset neurotoxicity. For patients with hairy cell leukemia, cladribine is administered by continuous IV infusion over 7 consecutive days.

102.4.3.6 Nelarabine

Nelarabine [Arranon], approved in 2005, is an analog of guanosine. The drug is used for patients with either *T-cell acute lymphoblastic leukemia* or *T-cell lymphoblastic lymphoma* that has not responded to (or has stopped responding to) at least two chemotherapy regimens. Monotherapy with nelarabine can produce a complete response in some of these patients. The drug is administered IV and undergoes conversion to its active form—ara-GTP—within cells. Incorporation of ara-GTP into DNA then causes DNA fragmentation and apoptosis. The most common side effects are anemia, leukopenia, neutropenia, and thrombocytopenia. Potentially

fatal neurotoxicity—manifesting as paresthesias, ataxia, confusion, convulsions, and coma—is dose limiting. The recommended adult dosage is 1500mg/m² infused over 2 hours on days 1 and 5, repeated every 21 days.

^{10...} HYPOMETHYLATING AGENTS

^{102.5.1} Azacitidine

Azacitidine [Vidaza], approved in 2004, is the first representative of a new class of anticancer drugs: the hypomethylating agents. The drug, an analog of cytidine, becomes incorporated into DNA and then inhibits DNA methyltransferase, an enzyme that puts methyl groups onto DNA components. The resultant hypomethylation of DNA is believed to induce apoptosis and restore normal function to genes critical to cell differentiation and proliferation. *In vitro*, concentrations that cause maximal inhibition of DNA methylation do not cause significant inhibition of DNA synthesis. Azacitidine has one indication: *myelodysplastic syndrome*, a bone marrow disorder characterized by reduced blood cell counts and the potential to progress to acute myelogenous leukemia. Toxicities include myelosuppression, nausea and vomiting, and CNS depression. The initial dosage is 75 mg/m² subQ once a day for 7 days every 4 weeks.

1190

1191

^{102.5.2} Decitabine

Decitabine [Dacogen], like azacitidine, inhibits DNA methyltransferase, and thereby suppresses DNA methylation, leading to apoptosis and/or normalization of differentiation and proliferation. Like azacitidine, decitabine is used only for myelodysplastic syndrome. Toxicities include myelosuppression, nausea and vomiting, and a flu-like syndrome. A single dose consists of 15 mg/m² infused IV over 3 hours. The regimen consists of one dose every 8 hours for 72 hours, repeated every 6 weeks.

^{10...} ANTITUMOR ANTIBIOTICS

The antitumor antibiotics are cytotoxic drugs originally isolated from cultures of *Streptomyces*. In this section, we consider five antitumor antibiotics and three of their derivatives. The antitumor antibiotics and their derivatives are used only to treat cancer; they are not used to treat infections. All of these drugs injure cells through direct interaction with DNA. Because of poor GI absorption, they are all administered parenterally, almost always IV. The antitumor antibiotics fall into two major groups: anthracyclines and nonanthracyclines.

102.6.1 Anthracyclines

Five of the antitumor antibiotics are derivatives of anthracycline. All five cause severe bone marrow suppression, and all five can damage the heart. In some patients, cardiotoxicity has led to fatal heart failure. Treatment with dexrazoxane [Zinecard] offers some protection against cardiac damage.

102.6.1.1 Doxorubicin, Conventional

Doxorubicin, a derivative of anthracycline, is active against a broad spectrum of neoplastic diseases. Unfortunately, cardiotoxicity limits its utility. Doxorubicin is available in two formulations: conventional [Adriamycin] and liposomal [Doxil]. The conventional preparation is discussed here, and the liposomal preparation is discussed immediately below.

102.6.1.1.1 Mechanism of Action.

Doxorubicin is a planar (flat) molecule that kills cells by two related mechanisms: *intercalation with DNA* and *inhibition of topoisomerase II*. We can understand intercalation by envisioning the stacked base pairs of DNA as having a structure like that of a stack of coins. Having a coin-like shape itself, doxorubicin is able to slip between base pairs of DNA, after which it becomes bound to DNA. This process (intercalation) distorts DNA structure. As a result, DNA po-lymerase and RNA polymerase are unable to use DNA as a template, and hence synthesis of DNA and RNA is inhibited.

While bound to DNA, doxorubicin forms a complex with topoisomerase II, an enzyme that cleaves and then repairs DNA strands. Doxorubicin allows topoisomerase II to cleave DNA, but prevents subsequent DNA repair. In the absence of DNA repair, apoptosis results. Topoisomerase is discussed further under *Topoisomerase Inhibitors* below. Doxorubicin is *cell-cycle phase nonspecific*.

102.6.1.1.2 Pharmacokinetics.

Doxorubicin is administered by IV infusion and undergoes rapid uptake by tissues. The drug does not cross the blood-brain barrier. Much of each dose is metabolized in the liver. Accordingly, dosage must be reduced in patients with hepatic impairment. Doxorubicin and its metabolites are eliminated primarily in the bile.

102.6.1.1.3 Therapeutic Uses.

Doxorubicin is active against many neoplastic diseases. The drug is employed to treat solid tumors and disseminated cancers. Specific indications include *Hodgkin's and non-Hodgkin's lymphomas, sarcomas of soft tissue and bone, and various carcinomas, including carcinoma of the lung, stomach, breast, ovary, testes, and thyroid.*

102.6.1.1.4 Toxicity.

102.6.1.1.4.1 Cardiotoxicity.

Doxorubicin can cause acute and delayed injury to the heart. Acute effects (dysrhythmias, electrocardiographic changes) can develop within minutes of administration. In most cases these reactions are transient, lasting no more than 2 weeks.

Delayed cardiotoxicity develops months to years after doxorubicin therapy, and manifests as heart failure secondary to diffuse cardiomyopathy (myofibril degeneration). The condition is often unresponsive to treatment. Delayed cardiac injury is directly related to the total cumulative dose: The risk of heart failure increases significantly as the cumulative lifetime dose rises above 550 mg/m². Accordingly, the total dose should not exceed this amount.

A relatively new drug—*dexrazoxane* [Zinecard]—can protect the heart from doxorubicin, but at the expense of additional myelosuppression and possible reduction of antitumor activity. To protect the heart, dexrazoxane must first undergo conversion to a chelating agent within the body. In this active form, the drug binds intracellular iron, thereby preventing it from interacting with doxorubicin. In clinical trials, dexrazoxane significantly decreased the incidence of doxorubicin-induced heart failure. However, treatment did have two complications: (1) the drug appeared to intensify myelosuppression, and (2) it may have reduced the anticancer effects of doxorubicin. To ensure that the benefits of chemotherapy are not compromised, dexrazoxane is approved only for patients who have already received 300 mg/m² of doxorubicin. Furthermore, the drug is approved only for patients receiving doxorubicin for *breast cancer* (even though doxorubicin is used to treat other malignancies). Why the restriction? Because intensification of myelosuppression may be greater in patients with tumors other than breast cancer.

Angiotensin-converting enzyme (ACE) inhibitors, such as ramipril, can improve symptoms of cardiomyopathy. Furthermore, if given early, ACE inhibitors may be able to *prevent* cardiac damage.

102.6.1.1.4.2 Other Toxicities.

Acute toxicity usually manifests as nausea and vomiting. Because of its vesicant properties, doxorubicin can cause severe local injury if extravasation occurs. In addition, the drug imparts a harmless red color to urine and sweat; patients should be forewarned. The usual dose-limiting toxicity is bone marrow suppression. Neutropenia develops in about 70% of patients. Thrombocytopenia and anemia may also occur. Additional delayed toxicities include alopecia, stomatitis, anorexia, conjunctivitis, and pigmentation in the extremities.

102.6.1.2 Doxorubicin, Liposomal

Liposomal doxorubicin [Doxil]—a reformulation of conventional doxorubicin—was created to increase delivery of the drug to tumor cells, and decrease its uptake by normal cells. The preparation consists of doxorubicin encapsulated within lipid vesicles (liposomes), which are coated with polyethylene glycol to avoid immune removal, and thereby prolong their stay in the bloodstream. While in the vicinity of tumor cells and normal cells, the liposomes slowly release doxorubicin. However, because capillaries in tumors are more leaky than capillaries in healthy tissue, the liposomes have better access to tumor cells, and hence show some tumor selectivity. Liposomal doxorubicin is administered as a 30-minute IV infusion.

1191

The preparation has four indications: *AIDS-related Kaposi's sarcoma, metastatic ovarian cancer, metastatic breast cancer, and multiple myeloma.*

1192

Major dose-limiting toxicities are bone marrow suppression and heart failure. In addition, liposomal doxorubicin can cause hand-and-foot syndrome and infusion-related symptoms (back pain, flushing, and chest tightness), which are seen in 5% to 10% of patients. As a rule, the infusion symptoms begin within 5 minutes of infusion onset, subside when the infusion is interrupted, and don't return when the infusion is resumed at a slower rate.

102.6.1.3 Daunorubicin

Daunorubicin is nearly identical in structure to doxorubicin, and shares many of its properties. Like doxorubicin, daunorubicin intercalates with DNA and thereby inhibits DNA and RNA synthesis. The drug can act during all phases of the cell cycle, but cytotoxicity is greatest during S phase.

Like doxorubicin, daunorubicin is available in two formulations: conventional [Cerubidine] and liposomal [DaunoXome]. The conventional formulation is used for induction therapy of leukemia. The liposomal formulation is used for HIV-associated Kaposi's sarcoma.

As with doxorubicin, the major dose-limiting toxicities are bone marrow suppression and heart failure. In addition, daunorubicin may cause nausea, vomiting, stomatitis, and alopecia. Like doxorubicin, daunorubicin imparts a harmless red color to urine and tears.

102.6.1.4 Epirubicin

102.6.1.4.1 Mechanism of Action and Therapeutic Use.

Epirubicin [Ellence], an analog of doxorubicin, is indicated for IV adjuvant therapy of *breast cancer*, following surgical removal of the primary tumor in patients who have axillary node involvement. Combined therapy with cyclophosphamide and fluorouracil is usually employed. Epirubicin is given in repeated 21-day cycles consisting of either (1) 100 mg/m² on day 1 only, or (2) 60 mg/m² on days 1 and 8. For most patients, epirubicin offers no advantages over doxorubicin.

Like doxorubicin, epirubicin (1) intercalates DNA and thereby inhibits synthesis of DNA, RNA, and proteins; and (2) causes DNA strand breaks by disrupting function of topoisomerase II. Epirubicin is considered cell-cycle phase nonspecific. However, cytotoxicity is maximal during S and G₂ phases.

102.6.1.4.2 Pharmacokinetics.

Epirubicin is widely distributed following IV infusion. The drug undergoes hepatic metabolism followed by excretion in the bile and urine. Elimination is slowed in patients with liver dysfunction secondary to hepatic metastases or other causes.

102.6.1.4.3 Adverse Effects.

Epirubicin can cause a variety of serious adverse effects. As with doxorubicin, bone marrow suppression and cardiotoxicity are dose limiting. To reduce the risk of severe cardiac damage, the total cumulative dose should not exceed 900 mg/m² (compared with 550 mg/m² for doxorubicin). Fortunately, when epirubicin is used for adjuvant therapy, the cumulative dose should be well below the safe limit. Extravasation can result in severe local tissue necrosis. Additional adverse effects include alopecia, nausea, vomiting, mucositis, and red discoloration of urine. In animals, epirubicin is embryotoxic and teratogenic; studies in pregnant women have not been performed.

102.6.1.5 Idarubicin

Idarubicin [Idamycin] is a structural analog of daunorubicin and doxorubicin. The drug has one approved indication: induction therapy of *acute myelogenous leukemia* in adults. Like other anthracyclines, idarubicin (1) intercalates DNA to disrupt synthesis of DNA, RNA, and proteins; and (2) causes DNA strand breaks by disrupting function of topoisomerase II. Idarubicin works best during S phase and G₂ but is still considered phase nonspecific.

Following IV infusion, the drug undergoes rapid and widespread distribution. Elimination is by hepatic metabolism followed by biliary excretion. The principal dose-limiting toxicity is bone marrow suppression. Like other anthracyclines, idarubicin is cardiotoxic, especially when the cumulative dose exceeds 150 mg/m². Additional toxicities include nausea, vomiting, alopecia, and stomatitis. Idarubicin is a vesicant and can cause severe local injury upon extravasation.

102.6.1.6 Mitoxantrone

Although not a true anthracycline, mitoxantrone [Novantrone] is a close relative of these drugs and shares most of their properties. Like the anthracyclines, mitoxantrone appears to act by two mechanisms: (1) intercalation of DNA and (2) promotion of DNA strand breakage secondary to inhibition of topoisomerase II. The drug is cell-cycle phase nonspecific. Principal applications are *prostate cancer* and *acute nonlymphocytic leukemias*. In addition, the drug is used to reduce neurologic disability in people with multiple sclerosis (see [Chapter 23](#)).

Mitoxantrone is administered intravenously and undergoes rapid and widespread distribution. Elimination occurs slowly, primarily by hepatic metabolism and biliary excretion. The major dose-limiting toxicities are bone marrow suppression and injury to the heart, especially when the cumulative dose exceeds 120 mg/m². Other important toxicities—nausea, vomiting, alopecia, and mucositis—are less severe than with doxorubicin. Some patients have developed acute myelogenous leukemia while using the drug. Mitoxantrone imparts a harmless blue-green tint to the urine, skin, and sclera; patients should be forewarned.

102.6.2 Nonanthracyclines

There are three nonanthracycline antitumor antibiotics: dactinomycin, bleomycin, and mitomycin. In contrast to anthracyclines, nonanthracyclines do not injure the heart. However, these drugs do have serious toxicities of their own.

102.6.2.1 Dactinomycin (Actinomycin D)

102.6.2.1.1 Actions and Uses.

Like doxorubicin, dactinomycin [Cosmegen] is a planar molecule that intercalates DNA, and thereby distorts DNA structure. As a result, RNA polymerase is unable to use DNA as a template, and hence synthesis of RNA (and proteins) is inhibited. Unlike RNA polymerase, DNA polymerase is relatively insensitive to the change in DNA. Consequently, DNA synthesis is not suppressed. Dactinomycin is *phase nonspecific*. Major indications for dactinomycin are *Wilms' tumor* and *rhabdomyosarcoma*. Other indications include *choriocarcinoma*, *Ewing's sarcoma*, *Kaposi's sarcoma*, and *testicular cancer*.

102.6.2.1.2 Pharmacokinetics.

Administration is by IV infusion. Because of tissue uptake and binding to DNA, dactinomycin is rapidly cleared from the blood. The drug does not cross the blood-brain barrier. Elimination occurs slowly by biliary and renal excretion.

102.6.2.1.3 Toxicity.

Dose-limiting toxicities are bone marrow suppression and oral and GI mucositis. Nausea and vomiting may be severe. Other toxicities include diarrhea, alopecia, folliculitis, and, in previously irradiated areas, dermatitis. Dactinomycin is a strong vesicant, and hence extravasation will cause severe local injury.

102.6.2.2 Bleomycin

The preparation of bleomycin [Blenoxane] used clinically contains a mixture of glycopeptides. The major components are bleomycin A₂ and bleomycin B₂. Bleomycin is unusual among the cytotoxic agents in that it causes very little bone marrow suppression. However, it can cause severe injury to the lungs. Because myelosuppression is minimal, bleomycin could be especially useful in combination chemotherapy, although the potential for lung injury often limits its use. Bleomycin binds to DNA, causing chain scission and fragmentation. The drug is most effective during G₂.

Therapeutic uses include *testicular carcinomas* (embryonal cell, choriocarcinoma, teratocarcinoma), *lymphomas* (Hodgkin's, reticulum cell sarcoma, lymphosarcoma), and *squamous cell carcinomas* (head, neck, larynx, cervix, penis, vulva, skin). The most common uses are testicular cancer and Hodgkin's disease, for which bleomycin is employed as a component of curative regimens.

Administration is parenteral (IM, IV, subQ, intrapleural). High concentrations are achieved in the skin and lungs. The drug does not enter the CNS. Most tissues contain large amounts of bleomycin hydrolase, an enzyme that renders the drug inactive. However, cells of the skin and lungs, which are sites of toxicity, lack this enzyme. Most of each dose is excreted unchanged in the urine.

The major dose-limiting toxicity is injury to the lungs, which occurs in about 10% of patients. Injury manifests initially as pneumonitis. In about 1% of patients, pneumonitis progresses to severe pulmonary fibrosis and death. Pulmonary function should be monitored and bleomycin discontinued at the first sign of adverse changes. Additional toxicities include stomatitis, alopecia, and skin reactions (hyperpigmentation, hyperkeratosis, pruritus erythema, ulceration, vesiculation). Nausea and vomiting are usually mild. Unlike most other cytotoxic anticancer drugs, bleomycin exerts minimal toxicity to bone marrow. About 1% of patients with lymphomas experience a unique hypersensitivity reaction, characterized by fever, chills, confusion, hypotension, and wheezing.

102.6.2.3 Mitomycin

Mitomycin [Mutamycin] is a prodrug that is converted to its active form within cells. Following activation, it functions as a bifunctional or trifunctional alkylating agent. Cell death is caused by cross-linking DNA with resultant blockade of DNA synthesis. Mitomycin may also induce strand scission. The drug is active during all phases of the cell cycle, but toxicity is greatest during late G₁ and early S phase.

Mitomycin is labeled for *disseminated adenocarcinoma of the stomach and pancreas*. Unlabeled uses include *carcinomas of the colon, rectum, esophagus, lung, breast, cervix, and bladder*.

Mitomycin is administered by IV infusion and is distributed widely, but not to the CNS. The drug is rapidly metabolized in the liver to active and inactive metabolites. Metabolites are excreted in the urine.

The major dose-limiting toxicity is delayed bone marrow suppression; nadirs for neutropenia and thrombocytopenia usually occur 4 to 6 weeks after treatment. Mitomycin can also cause hemolytic uremic syndrome, a serious disorder characterized by microangiopathic hemolytic anemia, thrombocytopenia, and irreversible renal failure. Other toxicities include nausea, vomiting, stomatitis, alopecia, and pulmonary toxicity. Mitomycin is a vesicant and can cause severe local injury upon extravasation.

1192

1193

^{10...} MITOTIC INHIBITORS

Mitotic inhibitors are drugs that act during M phase to prevent cell division. There are two groups of these drugs: vinca alkaloids and taxanes.

^{102.7.1} Vinca Alkaloids

The vinca alkaloids are derived from *Vinca rosea* (the periwinkle plant), hence the group name. *Vincristine* and *vinblastine* are the most important members. These two agents have nearly identical structures and share the same mechanism of action. However, they have quite different toxicities: Vincristine is toxic to peripheral nerves, but does little damage to bone marrow; conversely, vinblastine can cause significant bone marrow suppression, but is much less harmful to nerves.

^{102.7.1.1} Vincristine

^{102.7.1.1.1} Mechanism of Action.

Vincristine [Oncovin, Vincasar] blocks mitosis during metaphase, and hence is M-phase specific. The drug blocks mitosis by disrupting the assembly of microtubules, the filaments that move chromosomes during cell division. To block microtubule assembly, vincristine binds with *tubulin*, the major component of microtubules. In the absence of microtubules, cell division is blocked at metaphase. Metaphase block is a potent signal for apoptosis (programmed cell death).

^{102.7.1.1.2} Pharmacokinetics.

Because of low and erratic oral absorption, vincristine must be given IV. The drug leaves the vascular system and enters tissues, where it becomes tightly but reversibly bound. Penetration to the CNS is poor. Most of each dose undergoes hepatic metabolism followed by biliary excretion. Only 12% is eliminated in the urine.

^{102.7.1.1.3} Therapeutic Uses.

Vincristine is bone marrow sparing. Accordingly, the drug is ideal for combination chemotherapy. Indications include *Hodgkin's and non-Hodgkin's lymphomas, acute lymphocytic leukemia, Wilms' tumor, rhabdomyosarcoma, Kaposi's sarcoma, breast cancer, and bladder cancer.*

102.7.1.1.4 Toxicity.

Peripheral neuropathy is the major dose-limiting toxicity. Vincristine injures neurons by disrupting neurotubules, structures that are required for axonal transport of enzymes and organelles. Injury to neurotubules results from binding to tubulin, the same protein found in microtubules. Nearly all patients experience symptoms of sensory or motor nerve injury (eg, decreased reflexes, weakness, paresthesias, sensory loss). Symptoms of injury to autonomic nerves (eg, constipation, urinary hesitancy) are less common, occurring in 30% to 50% of patients. Because vincristine does not readily enter the CNS, injury to the brain is minimal.

In contrast to most cytotoxic anticancer drugs, *vincristine causes little toxicity to bone marrow*. As a result, the drug is especially desirable for combined therapy with other anticancer drugs.

Vincristine is a vesicant and can cause severe local injury if extravasation occurs. Alopecia develops in about 20% of patients. Significant nausea and vomiting are uncommon.

102.7.1.2 Vinblastine

Vinblastine [Velban] is a structural analog of vincristine. The two drugs share the same mechanism of action: production of metaphase arrest through blockade of microtubule assembly. Like vincristine, vinblastine is administered IV, does not cross the blood-brain barrier, and is eliminated by biliary and urinary excretion. Indications include *Kaposi's sarcoma, Hodgkin's and non-Hodgkin's lymphomas, and carcinoma of the breast and testes*. The major dose-limiting toxicity is bone marrow suppression. (Note that vinblastine differs markedly from vincristine in this regard.) Neurotoxicity can occur, but is less common and less severe than with vincristine. Additional adverse effects include nausea, vomiting, alopecia, stomatitis, and severe local injury if extravasation should occur.

102.7.1.3 Vinorelbine

Vinorelbine [Navelbine] is a semisynthetic vinca alkaloid similar in structure and actions to vincristine and vinblastine. The drug is approved only for *non-small cell lung cancer*. Investigational uses include *breast cancer, ovarian cancer, and Hodgkin's disease*. Benefits derive from causing metaphase arrest through inhibition of microtubule assembly. Vinorelbine is administered IV, undergoes hepatic metabolism, and is eliminated primarily in the bile. Like vinblastine, and unlike vincristine, vinorelbine can cause profound bone marrow suppression; neutropenia develops in about 50% of patients. Peripheral neuropathy occurs, but is less severe than with vincristine. Rarely, vinorelbine causes interstitial pulmonary damage and adult

respiratory distress syndrome, typically within 1 week of treatment; most cases have been fatal. Accordingly, be alert for new-onset dyspnea, cough, hypoxia, and related signs of lung injury. Other adverse effects include alopecia, constipation, nausea, and vomiting, all of which are generally mild to moderate. Like vincristine and vinblastine, vinorelbine can cause local tissue necrosis if extravasation occurs.

102.7.2 Taxanes

102.7.2.1 Paclitaxel

102.7.2.1.1 Actions and Uses.

Paclitaxel [Taxol, Onxol, Abraxane] is a widely used drug that acts during late G₂ and M phase to promote formation of stable microtubule bundles, thereby inhibiting cell division and producing apoptosis. Paclitaxel (in combination with cisplatin) is approved as first-line therapy for advanced *ovarian cancer* and *non–small cell lung cancer* in patients who are not candidates for potentially curative surgery or radiation therapy. In addition, the drug is approved as second-line therapy for *AIDS-related Kaposi's sarcoma* and as adjuvant therapy combined with doxorubicin-containing regimens for women with *breast cancer*.

Investigational uses include *advanced head and neck cancer*, *adenocarcinoma of the upper GI tract*, and *leukemias*.

102.7.2.1.2 Pharmacokinetics.

Paclitaxel is administered by either a 3-hour or 24-hour infusion. The drug undergoes wide distribution, but not to the CNS. Very little is known about how paclitaxel is eliminated; small amounts appear in the urine and bile, but the fate of the remainder is unknown.

102.7.2.1.3 Formulations.

Paclitaxel is available in two IV formulations. The older of the two, sold as Taxol and Onxol, contains a solvent system (Cremaphor and alcohol) that can trigger severe hypersensitivity reactions. The newer formulation, sold as Abraxane, consists of paclitaxel bound to nanoparticles of albumin. Addition of water forms a suspension; no solvent is employed.

102.7.2.1.4 Toxicity.

Severe hypersensitivity reactions (hypotension, dyspnea, angioedema, urticaria) have occurred during infusion of Taxol and Onxol—but *not* Abraxane—apparently in response to the solvent employed. The risk of severe hypersensitivity reactions with Taxol and Onxol

1193

1194

can be minimized by pretreatment with a glucocorticoid (dexamethasone), histamine₁-receptor antagonist (diphenhydramine), and histamine₂-receptor antagonist (cimetidine). With Abraxane, no pretreatment is needed.

The major dose-limiting toxicity is *bone marrow suppression* (neutropenia). Peripheral neuropathy develops with repeated infusions and may also be dose limiting. Paclitaxel can affect the heart, causing bradycardia, second- and third-degree heart block, and even fatal myocardial infarction. Muscle and joint pain have occurred. Practically all patients experience sudden but reversible alopecia, which frequently involves the body as well as the scalp. Gastrointestinal reactions—nausea, vomiting, diarrhea, and mucositis—are generally mild.

102.7.2.2 Docetaxel

102.7.2.2.1 Actions, Uses, and Source.

Docetaxel [Taxotere] is similar in structure and actions to paclitaxel. Like paclitaxel, docetaxel stabilizes microtubules, and thereby inhibits mitosis. Docetaxel has three approved indications: (1) locally advanced or metastatic *breast cancer* that has progressed or relapsed despite prior chemotherapy, (2) locally advanced or metastatic *non-small cell lung cancer* that has advanced despite prior cisplatin-based therapy, and (3) advanced, hormone-refractory metastatic *prostate cancer* (in combination with prednisone). In clinical trials, docetaxel produced objective responses in over 40% of patients with breast cancer. Recommended dosages are 60 or 100 mg/m² (for breast cancer) and 75 mg/m² (for lung and prostate cancers). For all patients, docetaxel is infused IV over 1 hour every 3 weeks. Docetaxel is manufactured by a semisynthetic process that begins with a compound extracted from needles of the European yew tree.

102.7.2.2.2 Toxicity.

Significant *neutropenia* develops in virtually all patients. Docetaxel should be withheld if neutrophil counts fall below 1500/mm³. In clinical trials, death from sepsis occurred in 1% of patients with normal liver function and in 11% of patients with abnormal liver function. Because liver dysfunction increases the risk of death, docetaxel should be avoided if signs of liver disease are present (ie, plasma aminotransferase activity more than 1.5 times normal and alkaline phosphatase activity more than 2.5 times normal).

Severe *hypersensitivity* can occur. Manifestations include hypotension, bronchospasm, and generalized rash or erythema. Docetaxel should be avoided in patients who reacted strongly

to a previous dose or to any drug containing polysorbate 80 (the vehicle docetaxel is supplied in). To reduce hypersensitivity reactions, patients should take an oral glucocorticoid for 5 days, starting 1 day before each infusion.

Severe *fluid retention* can occur, especially in patients with abnormal liver function. Possible manifestations include generalized edema, dyspnea at rest, cardiac tamponade, pleural effusion requiring urgent drainage, and pronounced abdominal distention (from ascites). As with hypersensitivity reactions, fluid retention can be reduced by treatment with oral glucocorticoids, which are normally started the day before dosing and continued for 2 days after.

Additional common toxicities are anemia, nausea, diarrhea, stomatitis, fever, and neurosensory symptoms (paresthesias, pain).

102.7.3 Other Mitotic Inhibitors

102.7.3.1 Ixabepilone

Ixabepilone [Ixempra], approved in 2007, is a large cytotoxic molecule in the epothilone family. Like the taxanes, the drug binds to and stabilizes microtubules, and thereby causes mitotic arrest and apoptosis. At this time, ixabepilone is approved only for locally advanced or metastatic *breast cancer*. The drug may be used alone (after an anthracycline, a taxane, and capecitabine have failed) or combined with capecitabine (after an anthracycline and taxane have failed). Major toxicities are neutropenia, seen in 54% to 68% of patients, and peripheral sensory neuropathy. Less serious side effects include fatigue, myalgia, arthralgia, alopecia, nausea, vomiting, diarrhea, and stomatitis/mucositis. Ixabepilone is a substrate for the isozyme of cytochrome P450 CYP3A4, and hence its levels can be increased by drugs that inhibit this isozyme, and reduced by drugs that induce it. In patients taking a strong CYP3A4 inhibitor, dosage of ixabepilone should be reduced by 50%. In patients with significant liver impairment, evidenced by elevated serum bilirubin or liver transaminases, dosage of ixabepilone in monotherapy should be reduced, and the combination of ixabepilone plus capecitabine should be avoided. When ixabepilone is combined with capecitabine, the usual dosage is 40 mg/m² IV every 3 weeks.

102.7.3.2 Estramustine

Estramustine [Emcyt] is a hybrid molecule composed of estradiol and a nitrogen mustard. Like the other drugs discussed in this section, estramustine binds microtubules, and thereby causes mitotic arrest. The pharmacology of estramustine is discussed further in [Chapter 102](#).

^{10...} TOPOISOMERASE INHIBITORS

Topoisomerases are nuclear enzymes that alter the shape (topology) of supercoiled DNA. Without the actions of topoisomerases, the double helix would be too tangled to permit DNA replication, RNA synthesis, or DNA repair. How do topoisomerases alter DNA configuration? They make a cut in the DNA strand—which permits the strand to relax in the vicinity of the cut—and then later they reseal the cut. There are two types of topoisomerase, known as topoisomerase I and topoisomerase II. Topoisomerase I makes single-strand cuts, and topoisomerase II makes double-strand cuts. Of the four topoisomerase inhibitors in current use, two—topotecan and irinotecan—inhibit topoisomerase I, and the other two—etoposide and teniposide—inhibit topoisomerase II. The actions of these drugs are partly like those of the antitumor antibiotics discussed above, which inhibit topoisomerase II and intercalate DNA.

^{102.8.1} Topotecan

^{102.8.1.1} Mechanism of Action.

Topotecan [Hycamtin], an inhibitor of topoisomerase I, binds to the DNA–topoisomerase I complex. The drug does not prevent topoisomerase I from making a single-strand cut in DNA, but does prevent the enzyme from resealing the cut. As a result, there is an accumulation of DNA with multiple single-strand cuts. Of note, these single-strand cuts, by themselves, are not harmful: If the drug is removed, the cuts can be repaired. However, if the cell attempts to replicate DNA while the drug is still present, irreversible double-strand breaks will be produced, thereby causing cell death. Because ongoing replication of DNA is needed to kill the cell, topotecan is most active in S phase.

^{102.8.1.2} Therapeutic Uses.

Topotecan is approved for *small cell lung cancer* and *metastatic cancer of the ovary* refractory to prior chemotherapy. A single course of treatment consists of 1.5 mg/m² infused IV over 30 minutes on 5 consecutive days. Courses can be repeated after a 16-day hiatus. At least four courses are recommended.

^{102.8.1.3} Toxicity.

Bone marrow suppression is the dose-limiting toxicity. Neutropenia occurs in 98% of patients, thereby posing a risk of serious infection. Anemia and thrombocytopenia are also common, and frequently require transfusion of platelets and red blood cells. Because of myelosuppression, frequent counts of peripheral blood cells should be performed. If the neutrophil count is below

1500 cells/mm³, topotecan should be withheld. Other side effects include alopecia, nausea, vomiting, diarrhea, stomatitis, abdominal pain, and headache.

102.8.2 Irinotecan

102.8.2.1 Actions and Uses.

Like topotecan, irinotecan [Camptosar] and its active metabolite inhibit topoisomerase I. As a result, DNA replication is impaired. Cytotoxic effects become apparent during the S phase of the cell cycle. Irinotecan is approved for first-line treatment of metastatic *colorectal cancer* (in combination with fluorouracil) and for second-line treatment of colorectal cancer that has progressed despite treatment with fluorouracil alone. Investigational uses include *advanced cancer of the breast, ovary, lung, and stomach*. For colorectal cancer, the recommended dosage is 125 mg/m² infused IV over 90 minutes once a week for 4 weeks. In clinical trials, this dosage produced an objective response (complete or partial) in 15% of patients. The average response duration was 5.8 months.

102.8.2.2 Metabolic Activation and Inactivation.

Irinotecan is converted to its active metabolite (SN-38) in the liver. The metabolite, in turn, is converted to an inactive product by UDP-glucuronosyltransferase 1A1 (UGT1A1). In some patients, the genes that code for UGT1A1 are abnormal. As a result, inactivation of irinotecan is delayed and drug levels rise, thereby increasing the intensity of adverse effects. A genetic test, called Invader UGT1A1, can detect mutations in the genes that code for UGT1A1. In patients who have such mutations, a reduction in irinotecan dosage should be considered.

102.8.2.3 Adverse Effects.

Two types of *severe diarrhea* can occur: early and late. Early diarrhea occurs in 50% of patients; late diarrhea occurs in 88%. Early and late diarrhea differ with respect to cause and treatment. Early diarrhea occurs within 24 hours of infusion onset. The cause is excessive cholinergic stimulation of the GI tract. Accordingly, early diarrhea can be suppressed with IV atropine. Late diarrhea develops 24 hours or more after the infusion. It can be prolonged, causing severe dehydration and electrolyte imbalance, and can thereby pose a threat to life.

Late diarrhea should be treated immediately with loperamide. Fluid and electrolytes should be replaced as needed.

Myelosuppression can result in neutropenia (54%) and anemia (61%). Serious thrombocytopenia is uncommon. Sepsis secondary to neutropenia has resulted in death. If the neutrophil count falls below 500/mm³, irinotecan should be temporarily withheld.

In addition to diarrhea and myelosuppression, irinotecan can cause nausea (86%), vomiting (67%), asthenia (76%), alopecia (61%), abdominal discomfort (57%), anorexia (55%), fever (45%), and weight loss (30%). Less common side effects include stomatitis, dyspepsia, headache, cough, rhinitis, insomnia, and rash.

102.8.3 Etoposide

Etoposide [VePesid, Toposar, Etopophos], a drug derived from podophyllotoxin (a naturally occurring plant alkaloid), is an inhibitor of topoisomerase II. Etoposide does not prevent topoisomerase II from making double-strand breaks in DNA, but it does prevent the enzyme from resealing those breaks. Cell death results from accumulation of DNA with multiple breaks. Cells in S and G₂ phase are most sensitive. Etoposide is approved only for *refractory testicular cancer* and *small cell cancer of the lung*, but is used against many other tumors.

Administration is PO and IV. Plasma protein binding is high. Penetration to the CNS is low. Etoposide is eliminated by hepatic metabolism and renal excretion, and hence dosage should be reduced in patients with liver or renal impairment.

The major dose-limiting toxicity is bone marrow suppression. Other toxicities include alopecia, mucositis, and, rarely, peripheral neuropathy. Early adverse effects include nausea, vomiting, diarrhea, and fever.

With two etoposide products—VePesid and Toposar—hypotension can occur with rapid IV administration. The cause is the organic diluent used to solubilize these products, not the etoposide itself. Hypotension with these products can be avoided by diluting them in sufficient intravenous fluid. Hypotension is not a problem with Etopophos (etoposide phosphate), because this product is soluble in water, and hence the organic solubilizer is not needed.

102.8.4 Teniposide

Teniposide [Vumon] is an analog of etoposide and has the same mechanism of action: inhibition of topoisomerase II. The drug's only approved indication is *refractory acute lymphoblastic leukemia of childhood*.

Administration is by slow IV infusion. Most of each dose becomes bound to plasma proteins. Penetration to the CNS is poor. Elimination is by hepatic metabolism and renal excretion.

The major dose-limiting toxicity is bone marrow suppression (neutropenia, thrombocytopenia, anemia). Severe hypersensitivity reactions (urticaria, angioedema, bronchospasm, hypotension) occur in about 5% of patients; symptoms can be suppressed with epinephrine. Secondary

leukemias have developed within 8 years of initial drug exposure. Other toxicities include nausea, vomiting, diarrhea, and alopecia.

^{10...} MISCELLANEOUS CYTOTOXIC DRUGS

^{102.9.1} Asparaginase

Asparaginase [Elspar] is an enzyme that converts asparagine, an essential amino acid, into aspartic acid. By converting asparagine to aspartic acid, the drug deprives cells of asparagine needed to synthesize proteins. However, not all cells are affected. In fact, toxicity from asparaginase is limited almost exclusively to leukemic lymphoblasts. Why? Because these cells are unable to manufacture their own asparagine, whereas normal cells can. Hence, normal cells are able to replace the asparagine that asparaginase took away, but leukemic lymphoblasts can't. Asparaginase appears to act selectively during G₁.

The only indication for asparaginase is *acute lymphocytic leukemia*. For induction of remission, asparaginase is usually combined with prednisone and vincristine, and perhaps daunorubicin or doxorubicin.

Administration is parenteral (IM and IV). Distribution is restricted to the vascular system. The drug does not cross the blood-brain barrier. Asparaginase is inactivated by serum proteases.

Asparaginase can cause severe adverse effects. However, the spectrum of toxicities differs from that of other anticancer drugs. By inhibiting protein synthesis, the drug can cause coagulation deficiencies and injury to the liver, pancreas, and kidneys. Symptoms of CNS depression, ranging from confusion to coma, develop in about 30% of patients. Nausea and vomiting can be intense and may limit the dose that can be tolerated. Because asparaginase is a foreign protein, hypersensitivity reactions are common; fatal anaphylaxis can occur, and hence facilities for resuscitation should be immediately available. In contrast to most other anticancer drugs, asparaginase does not depress the bone marrow, nor does it cause alopecia, oral mucositis, or intestinal ulceration.

^{102.9.2} Pegaspargase

Pegaspargase [Oncaspar] is a modified form of asparaginase that causes fewer hypersensitivity reactions. Otherwise, the drugs are very similar. They have the same mechanism of action (destruction of asparagine) and produce the same spectrum of adverse effects (hypersensitivity reactions, pancreatitis, coagulopathy, and liver and kidney impairment). Of the patients who had hypersensitivity reactions to asparaginase, about 30% also have them with pegaspargase.

Pegaspargase is indicated only for *acute lymphocytic leukemia*, and only in patients who had a hypersensitivity reaction to asparaginase. Administration is IM or IV.

102.9.3 Hydroxyurea

Hydroxyurea [Hydrea, Mylocel] inhibits DNA replication by suppressing synthesis of DNA precursors. Specifically, the drug inhibits ribonucleoside diphosphate reductase, the enzyme that converts ribonucleotides into their corresponding deoxyribonucleotides. In the absence of deoxyribonucleotides, DNA cannot be made. Hydroxyurea is S-phase specific.

The principal indication for hydroxyurea is *chronic myelogenous leukemia*. The drug is also used for *squamous cell carcinoma* and recurrent, metastatic, or inoperable *carcinoma of the ovary*. In addition, hydroxyurea can relieve symptoms and prolong life in patients with *sickle cell anemia* (see [Chapter 106](#)).

Hydroxyurea is rapidly absorbed following oral administration. Unlike most anticancer agents, hydroxyurea crosses the blood-brain barrier with ease. Part of each dose is metabolized in the liver. Parent drug and metabolites are eliminated primarily in the urine.

The principal dose-limiting toxicity is bone marrow suppression. The drug also causes nausea, vomiting, and dysuria. Neurologic deficits and stomatitis may occur, but these are rare.

Hydroxyurea is teratogenic in experimental animals. Hence, like most other anticancer agents, it should be avoided during pregnancy.

102.9.4 Mitotane

Mitotane [Lysodren] is a structural analog of two insecticides: DDD and DDT. For reasons that are not understood, the drug is selectively toxic to cells of the adrenal cortex, both normal and neoplastic. The only indication for mitotane is palliative therapy of inoperable *adrenocortical carcinoma*.

Mitotane is administered PO. About 40% is absorbed. The drug is distributed widely, but not to the CNS. Because of storage in tissues (primarily fat), active drug remains in the body for weeks after dosing has ceased. Elimination is by hepatic metabolism and renal excretion.

The principal dose-limiting toxicities are CNS depression, nausea, and vomiting. Because mitotane injures the adrenal cortex, adrenal insufficiency is likely. Accordingly, patients will require supplemental glucocorticoids, especially at times of stress. Dermatitis is common. Other adverse effects include visual disturbances; orthostatic hypotension; and renal damage, manifested as hematuria, hemorrhagic cystitis, and albuminuria. Mitotane does not cause the

toxicities associated with most other anticancer drugs (bone marrow suppression, alopecia, oral and GI ulceration).

102.9.5 Procarbazine

102.9.5.1 Mechanism of Action.

Procarbazine [Matulane] is a prodrug that undergoes conversion to active metabolites in the liver. The metabolites are highly reactive molecules that alkylate DNA, and thereby suppress synthesis of DNA, RNA, and protein. The precise cause of cell death is unknown. Procarbazine is cell-cycle phase nonspecific.

102.9.5.2 Pharmacokinetics.

Procarbazine is readily absorbed following oral administration, but undergoes rapid and extensive hepatic metabolism. Active metabolites are highly lipid soluble and cross the blood-brain barrier with ease. Procarbazine and its metabolites are excreted primarily in the urine.

102.9.5.3 Therapeutic Uses.

The major uses for procarbazine are *Hodgkin's disease*, *non-Hodgkin's lymphoma*, and *primary brain cancer*. For Hodgkin's disease, procarbazine is combined with mechlorethamine, vincristine [Oncovin], and prednisone in the so-called MOPP regimen, formerly the regimen of choice in newly diagnosed patients.

102.9.5.4 Toxicity.

The usual dose-limiting toxicity is bone marrow suppression. Nausea and vomiting may also be dose limiting. Other adverse effects include peripheral neuropathy, CNS depression, secondary leukemias, and sterility, especially in males.

1195

102.9.5.5 Drug Interactions.

Because of its CNS effects, procarbazine should not be combined with CNS depressants (eg, barbiturates, phenothiazines, opioids). Ingestion of alcohol can induce a disulfiram-like response. Because procarbazine inhibits monoamine oxidase, there is a risk of severe hypertension in response to sympathomimetic drugs, tricyclic antidepressants, and tyramine-rich foods.

1196

102.9.6 Dacarbazine

102.9.6.1 Actions and Uses.

Dacarbazine [DTIC-Dome] is a prodrug that undergoes activation in the liver. Although the precise mechanism of cell kill is unknown, there is evidence for alkylation of DNA, inhibition of DNA and RNA synthesis, and interaction with sulfhydryl groups on proteins. Dacarbazine is considered cell-cycle phase nonspecific. Principal indications are metastatic *malignant melanoma* and *Hodgkin's disease*.

102.9.6.2 Pharmacokinetics.

Gastrointestinal absorption of dacarbazine is erratic, and hence administration is done IV. Penetration to the CNS is poor. Elimination is by hepatic metabolism and renal excretion.

102.9.6.3 Toxicity.

Bone marrow suppression is the usual dose-limiting toxicity. Nausea and vomiting occur in most patients, occasionally requiring cessation of treatment. Other toxicities include a flu-like syndrome, hepatic necrosis, photosensitivity, and burning pain along the injection site.

102.9.7 Altretamine (Hexamethylmelamine)

Altretamine [Hexalen], formerly known as hexamethylmelamine, is indicated for palliative therapy of persistent or recurrent *ovarian cancer*. Altretamine is a prodrug that is converted to active metabolites in the body. As with procarbazine and dacarbazine, the active metabolites have alkylating activity. However, the precise mechanism of cell kill has not been established. Altretamine is well absorbed following oral dosing, but undergoes rapid and extensive hepatic metabolism. The metabolites are excreted in the urine. The principal dose-limiting toxicity is bone marrow suppression. However, nausea and vomiting can also limit dosage. Peripheral sensory neuropathy is common. Central neurotoxicity (tremors, ataxia, vertigo, hallucinations, seizures, depression) is less common. Because of peripheral and central neurotoxicity, patients should receive regular neurologic evaluations.

102.9.7.1 KEY POINTS

- Cytotoxic anticancer drugs act directly on cancer cells and healthy cells to produce cell death.

- Cell-cycle phase-specific drugs are effective only during a specific phase of the cell cycle (eg, S phase, M phase). Accordingly, they are only active against cells that are participating in the cell cycle. Cells in G_0 are spared.
- To be effective, phase-specific drugs must be present as neoplastic cells cycle through the phase in which the drugs act. In practical terms, this means that phase-specific drugs must be in the blood continuously over a long time.
- Cell-cycle phase-nonspecific drugs can affect cells during any phase of the cell cycle, including G_0 .
- Although phase-nonspecific drugs can inflict biochemical lesions at any time during the cell cycle, they usually are more toxic to proliferating cells than to cells in G_0 . Why? Because (1) G_0 cells often have time to repair drug-induced damage before it can result in significant harm, and (2) toxicity may not become manifest until the cells attempt to divide.
- About 50% of the cytotoxic anticancer drugs are phase specific; the rest are phase nonspecific.
- Alkylating agents injure cells primarily by forming covalent bonds with DNA.
- Bifunctional alkylating agents form cross-links in DNA, and thereby prevent DNA replication. Bifunctional agents are more effective than monofunctional agents.
- Because alkylation reactions can take place at any time during the cell cycle, alkylating agents are considered cell-cycle phase nonspecific.
- Cyclophosphamide, the most widely used alkylating agent, is active against a broad spectrum of neoplastic diseases.
- Antimetabolites are analogs of important natural metabolites, and hence are able to disrupt critical metabolic processes, especially DNA replication.
- Most antimetabolites are S-phase specific.
- Methotrexate, a folic acid analog, prevents conversion of folic acid to its active form. Cell kill results primarily from disruption of DNA synthesis.

- High doses of methotrexate coupled with leucovorin rescue can be used to treat methotrexate-resistant tumors. This technique can be dangerous in that failure to give sufficient leucovorin at the right time can be lethal.
- Cytarabine, a pyrimidine analog, undergoes intracellular activation followed by incorporation into DNA, where it acts to inhibit DNA synthesis.
- Fluorouracil, a uracil analog, undergoes intracellular activation, after which it inhibits thymidylate synthetase, thereby depriving cells of thymidylate needed to make DNA.
- Antitumor antibiotics are used to treat cancer, not infections.
- Antitumor antibiotics fall into two major groups: anthracyclines (which damage the heart) and nonanthracyclines (which don't).
- Doxorubicin is an anthracycline-type antitumor antibiotic. To reduce the risk of heart failure, the cumulative lifetime dose should be kept below 550 mg/m². The risk can be further reduced with dexrazoxane, a drug that helps protect the heart from doxorubicin.
- Doxorubicin is a planar molecule that intercalates DNA, thereby distorting DNA structure. As a result, DNA polymerase and RNA polymerase are unable to use DNA as a template, and hence synthesis of DNA, RNA, and proteins is disrupted. Doxorubicin also disrupts the function of topoisomerase II, thereby causing strand breakage. This may be the primary mechanism of cell kill.
- Vincristine and vinblastine block assembly of the microtubules that move chromosomes during cell division. Accordingly, the drugs are M-phase specific.
- Vincristine is toxic to peripheral nerves, but does not significantly suppress bone marrow function. Because it spares bone marrow, vincristine can be safely combined with drugs that suppress bone marrow.
- In contrast to vincristine, vinblastine causes significant bone marrow suppression but is relatively harmless to peripheral nerves.
- Asparaginase converts asparagine into aspartic acid, and thereby deprives cells of asparagine needed to make proteins. Cytotoxicity is limited primarily to leukemic lymphoblasts. Why? Because these cells are unable to manufacture their own asparagine, whereas normal cells can.

¹⁰² CHAPTER 102 Anticancer Drugs II: Hormonal Agents, Biologic Response Modifiers, and Targeted Drugs

TIMOTHY McGUIRE

RICH LEHNE

In this chapter, we continue our discussion of anticancer agents, focusing on three large groups of drugs: hormonal agents, biologic response modifiers, and targeted drugs. The hormonal agents, used primarily for breast cancer and prostate cancer, mimic or block the actions of endogenous hormones ([Table 102-1](#)). The biologic response modifiers enhance immune attack against cancer cells. And the so-called targeted drugs bind with specific molecular targets on cancer cells, and thereby suppress tumor growth and promote cell death. Unlike the cytotoxic agents discussed in [Chapter 101](#), many of which are cell-cycle phase specific, the drugs addressed here lack phase specificity. In addition, many of these drugs lack the serious toxicities associated with cytotoxic agents, including bone marrow suppression, stomatitis, alopecia, and severe nausea and vomiting. Nonetheless, these drugs do have severe toxicities of their own.

^{10...} GLUCOCORTICOIDS

The basic pharmacology of the glucocorticoids is discussed in [Chapter 71](#) (Glucocorticoids in Nonendocrine Diseases). Discussion here is limited to their use in cancer. To benefit patients with cancer, dosages must be high, and hence, with long-term use, adverse effects are concern.

Glucocorticoids (eg, *prednisone*, *dexamethasone*) are used in combination with other agents to treat cancers arising from lymphoid tissue. Specific indications are *acute and chronic lymphocytic leukemias*, *Hodgkin's disease*, *non-Hodgkin's lymphomas*, and *multiple myeloma*. Glucocorticoids are beneficial in these cancers because they are directly toxic to lymphoid tissues: High-dose therapy causes suppression of mitosis, dissolution of lymphocytes, regression of lymphatic tissue, and cell death. When glucocorticoids are used acutely, toxicity is limited and manageable.

However, with prolonged treatment, multiple serious toxicities can occur, including osteoporosis, adrenal insufficiency, increased susceptibility to infection, GI ulcers, fluid and electrolyte disturbances, myopathy, growth retardation in children, and cutaneous atrophy. Unlike the short-term toxicities, these long-term toxicities are hard to manage.

In addition to their use against lymphoid-derived cancers, glucocorticoids are used to manage complications of cancer and cancer therapy. Specific benefits include suppression of

chemotherapy-induced nausea and vomiting, reduction of cerebral edema (caused by brain metastasis and irradiation to the brain), reduction of pain (caused by nerve compression or edema), and suppression of hypercalcemia in patients with steroid-responsive tumors. In addition, glucocorticoids can improve appetite and promote weight gain.

^{10...} DRUGS FOR PROSTATE CANCER

Cancer of the prostate is the most common cancer among men in the United States. In 2008, an estimated 186,320 new cases were diagnosed, and 28,660 were fatal. Treatment options include surgery, radiation, and drugs.

Standard treatment of *advanced prostate* cancer consists of *androgen deprivation*, which can be achieved by either (1) lowering testosterone production (through castration or drug therapy) or (2) blocking testosterone receptors with drugs. Both approaches deprive prostate cells of the testosterone they need for growth, and possibly for survival. Androgen deprivation does not cure prostate cancer, but it can slow disease progression and increase comfort. For nearly all patients, symptoms from metastases will abate or disappear. Unfortunately, benefits of androgen deprivation are time limited: After 18 to 24 months of treatment, disease progression often resumes. Androgen deprivation commonly causes hot flushes, impotence, reduced libido, decreased muscle mass, increased fat deposition, and decreased bone mass with associated increased risk of fractures.

1197

1198

TABLE 102-1 Hormones and Hormone Antagonists

Generic Name	Trade Name	Route	Indications
Glucocorticoids			
Prednisone	Deltasone, others	PO, IV	Acute and chronic lymphocytic leukemias, Hodgkin's and non-Hodgkin's lymphomas
Antiestrogens			
Tamoxifen	Nolvadex	PO	Breast cancer
Toremifene	Fareston	PO	Breast cancer
Raloxifene	Evista	PO	Breast cancer*
Fulvestrant	Faslodex	IM	Breast cancer
Aromatase Inhibitors			
Anastrozole	Arimidex	PO	Breast cancer
Letrozole	Femara	PO	Breast cancer
Exemestane	Aromasin	PO	Breast cancer
GnRH Agonists†			
Leuprolide	Eligard, Lupron Depot, Lupron, Viadur	IM, subQ, implant	Prostate cancer
Triptorelin	Trelstar Depot	IM	Prostate cancer
Goserelin	Zoladex	subQ	Prostate cancer
GnRH Antagonists			
Abarelix	Plenaxis	IM	
Degarelix	(not assigned yet)	SubQ	Prostate cancer
Androgen Receptor Blockers			
Flutamide	Eulexin	PO	Prostate cancer
Bicalutamide	Casodex	PO	Prostate cancer
Nilutamide	Nilandron	PO	Prostate cancer
Estrogens			
Diethylstilbestrol diphosphate	Stilphostrol	PO, IV	Prostate cancer
Ethinyl estradiol	Estinyl	PO	Prostate cancer

Estrogen Mustard			
Estramustine	Emcyt	PO	Prostate cancer
Progestins			
Medroxyprogesterone acetate	Depo-Provera	PO, IM	Renal and endometrial cancers
Megestrol acetate	Megace	PO	Breast and endometrial cancers
* Not approved by the Food and Drug Administration for this use.			
† Gonadotropin-releasing hormone agonists, also known as luteinizing hormone–releasing hormone (LHRH) agonists.			

For men with *localized prostate cancer*, surgery and radiation are the preferred treatments; brachytherapy (local implantation of radioactive seeds) is an option. For men with high-risk localized disease, androgen deprivation may be used as an adjunct.

103.2.1 Gonadotropin-Releasing Hormone Agonists

The gonadotropin-releasing hormone (GnRH) agonists suppress production of androgens by the testes. Hence, they can be looked on as indirect-acting antiandrogens. Currently, three GnRH agonists are available: leuprolide, triptorelin, and goserelin. All three are indicated for cancer of the prostate. In addition, leuprolide is used for endometriosis (see [Chapter 62](#)).

103.2.1.1 Leuprolide

103.2.1.1.1 Therapeutic Use.

Leuprolide [Eligard, Lupron, Lupron Depot, Viadur] is a synthetic analog of GnRH, also known as *luteinizing hormone–releasing hormone* (LHRH). Leuprolide is indicated for *advanced carcinoma of the prostate*. Palliation is the primary benefit. For patients with prostate cancer, leuprolide represents an alternative to orchiectomy (surgical castration). Leuprolide may be administered daily (subQ), monthly (IM), every 3 months (IM), or once a year (implant).

103.2.1.1.2 Mechanism of Action.

Cells of the prostate, both normal and neoplastic, are androgen dependent. Leuprolide provides palliation by suppressing androgen production in the *testes*. During the initial phase of treatment, leuprolide *mimics* GnRH. That is, the drug acts on the pituitary to *stimulate*

release of interstitial cell–stimulating hormone (ICSH), which acts on the testes to *increase* production of testosterone. As a result, there may be a transient “flare” in cancer symptoms.

1198

1199

However, with continuous exposure to leuprolide, pituitary GnRH receptors become desensitized. As a result, release of ICSH declines, causing testosterone production to decline too. After several weeks of treatment, testosterone levels are equivalent to those seen after surgical castration. Because leuprolide therapy mimics the effects of orchiectomy, treatment is often referred to as *chemical castration*.

It is important to note that leuprolide does *not* decrease production of *adrenal* androgens, which account for about 9% of the androgens in circulation. Hence, even though production of testicular androgens is essentially eliminated, adrenal androgens can provide some support for prostate cancer cells.

103.2.1.1.3 Co-treatment with an Androgen Receptor Blocker.

In patients receiving leuprolide, an androgen receptor blocker can help in two ways. Specifically, (1) it can prevent cancer cells from undergoing increased stimulation during the initial phase of GnRH therapy, when androgen production is increased; and (2) it can block the effects of adrenal androgens, whose production is not reduced by GnRH agonists. The current trend is to use an androgen receptor blocker during the first weeks of leuprolide therapy (to prevent leuprolide-induced tumor flare), after which the drug is discontinued unless there is tumor progression despite continued leuprolide treatment.

103.2.1.1.4 Adverse Effects.

Leuprolide is generally well tolerated. Hot flushes are the most common adverse effect, but these usually decline as treatment continues. Testosterone loss may also cause impotence and loss of libido, as well as reduction of muscle mass and increased adipose mass. During the initial weeks of treatment, elevation of testosterone levels may aggravate bone pain and urinary obstruction caused by prostate cancer. As a result, patients with vertebral metastases or pre-existing obstruction of the urinary tract may find treatment intolerable. As noted, concurrent treatment with an androgen receptor blocker can minimize these problems.

By suppressing testosterone production, leuprolide may increase the risk of osteoporosis and related fractures. Bone loss can be minimized by consuming adequate calcium and vitamin D, and by performing regular weight-bearing exercise. In addition, a bisphosphonate (eg,

zoledronic acid [Xometa]) might be used to preserve bone, although bisphosphonates are not specifically approved for leuprolide-induced osteoporosis.

103.2.1.2 Triptorelin

Triptorelin [Trelstar Depot, Trelstar LA] is a GnRH analog indicated for palliative treatment of *advanced prostate cancer*. The drug has the same mechanism of action and adverse effects as leuprolide, our prototype GnRH agonist. Triptorelin is administered by IM injection, either once a month [Trelstar Depot] or every 3 months [Trelstar LA].

103.2.1.3 Goserelin

Goserelin [Zoladex], like leuprolide, is a GnRH analog used for *advanced prostate cancer*. Both drugs share the same mechanism and adverse effects. Administration of goserelin is unique. The drug is formulated as a pellet that is supplied in a syringe with a 16-gauge needle. The pellet is implanted by subQ injection in the upper abdominal wall. Local anesthesia may be used prior to the injection.

103.2.2 Androgen Receptor Blockers

Androgen receptor blockers, or simply *antiandrogens*, are indicated only for advanced androgen-sensitive prostate cancer—and only in combination with surgical castration or with chemical castration using a GnRH agonist. Currently, three androgen receptor blockers are available: flutamide, bicalutamide, and nilutamide.

103.2.2.1 Flutamide

Flutamide [Eulexin], the first androgen antagonist available, is indicated for *prostate cancer* only. Benefits derive from blocking androgen receptors in tumor cells, thereby depriving them of needed androgenic support. In patients taking a GnRH agonist, flutamide can serve two purposes: (1) it can prevent tumor flare when GnRH therapy is started, and (2) it can block the effects of adrenal androgens. As a rule, the combination of an androgen antagonist plus a GnRH agonist—so-called complete androgen blockade—is reserved for suppressing the initial flare and for suppressing the tumor after it has stopped responding to a GnRH agonist alone. The combination is not used continuously because it does not increase survival, but does increase toxicity.

Flutamide is administered orally and undergoes rapid and complete absorption. Most of each dose is converted to an active metabolite on the first pass through the liver. Parent drug and metabolites are excreted in the urine. Dosing is done 3 times a day.

The common adverse effects are gynecomastia, nausea, vomiting, and diarrhea. Rarely, potentially fatal liver toxicity has occurred. To reduce the risk of serious harm, liver function should be assessed at baseline, monthly during the first 4 months of treatment, and periodically thereafter.

103.2.2.2 Bicalutamide

Like flutamide, bicalutamide [Casodex] is an androgen receptor blocker used for *advanced androgen-sensitive prostate cancer* in men undergoing therapy with a GnRH agonist (eg, leuprolide). The rationale for the combination is explained in the discussion of flutamide. When bicalutamide is used alone, the most common side effects are breast pain (38%) and gynecomastia (39%). When the drug is combined with leuprolide, the most common side effect is hot flushes (49%). Like flutamide, bicalutamide poses a small risk of liver injury, and hence liver function should be monitored. Bicalutamide is just as effective as flutamide, and dosing is more convenient (once a day vs. 3 times a day). As a result, bicalutamide is preferred.

103.2.2.3 Nilutamide

Like flutamide and bicalutamide, nilutamide [Nilandron] blocks receptors for androgens. The drug is approved for *metastatic prostate cancer* in men who have undergone surgical castration. Benefits derive from blocking the actions of adrenal androgens, which are not reduced by castration. In clinical trials, nilutamide reduced bone pain, prolonged progression-free survival, and increased median survival time. The recommended dosage is 300 mg once daily PO for 30 days followed by 150 mg once daily thereafter. Treatment should begin within 24 hours of castration.

Although nilutamide is structurally similar to flutamide, the drug is not as well tolerated. The most common adverse effects are hot flushes (67%), delayed adaptation to darkness (57%), nausea (24%), constipation (20%), insomnia (16%), and gynecomastia (11%). Other reactions occur less frequently, but are more dangerous. About 2% of patients experience dyspnea secondary to interstitial pneumonitis. If this develops, nilutamide should be withdrawn. About 1% of patients develop hepatitis. To ensure early diagnosis, liver function should be monitored.

^{103.2.3}Gonadotropin-Releasing Hormone Antagonists

Like the GnRH agonists, the GnRH *antagonists* suppress production of androgens by the testes, and hence can be viewed as indirect-acting antiandrogens. In contrast to the GnRH agonists, the GnRH antagonists do not produce an initial tumor flare. Currently, only two GnRH antagonists are available: abarelix and degarelix.

^{103.2.3.1} Abarelix

Abarelix [Plenaxis], approved in 2003, is a decapeptide indicated for palliative therapy of *advanced prostate cancer* in men who are not candidates for a GnRH agonist, and who don't want surgical castration. Benefits derive from suppressing testosterone production by the testes. The underlying mechanism is blockade of GnRH receptors in the pituitary, which decreases release of luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which in turn deprives the testes of the stimulus needed for testosterone production. After a few weeks of treatment, testosterone levels fall to those produced by castration. However, with prolonged treatment, efficacy may diminish. Accordingly, testosterone levels should be monitored every 2 months. Because abarelix works through direct blockade of GnRH receptors, the drug does not cause the initial surge in testosterone production seen with GnRH agonists, and hence there is no early tumor flare.

1199

1200

Abarelix is administered IM, and absorption is slow. Plasma levels peak in 3 days. Elimination is primarily by peptide bond hydrolysis, a process that occurs in the liver but does not involve cytochrome P450. The drug's half-life is 13 days.

Four of the most common adverse effects—hot flushes (79%), sleep disturbances (44%), breast enlargement (30%), and breast pain/nipple tenderness (20%)—result from testosterone deprivation. Other common complications are pain (31%), constipation (15%), and peripheral edema (15%). However, of greatest concern are *severe, immediate-onset allergic reactions*, which develop in about 4% of patients. Significant hypotension and fainting have occurred. These reactions can occur after any dose, and the risk rises as treatment continues. To reduce the risk of injury, patients should be observed for at least 30 minutes after each injection. Furthermore, the drug is only available to physicians who have enrolled in *Plenaxis PLUS* (Plenaxis User Safety Program), established to ensure that patients and physicians understand the benefits and risks of the drug.

103.2.3.2 Degarelix

Degarelix, approved in 2008, is indicated for advanced prostate cancer. Benefits derive from decreasing production of testosterone, which drops to castrate levels faster than with the GnRH agonists. Efficacy in prostate cancer is comparable to that of leuprolide (an androgen receptor blocker). Like abarelix, and in contrast to GnRH agonists, degarelix does not cause early tumor flare. The maintenance dosage is 80 mg subQ once a month.

103.2.4 Other Drugs for Prostate Cancer

103.2.4.1 Estrogens

In patients with prostate cancer, *diethylstilbestrol diphosphate* [Stilphostrol] and other estrogens can help. Benefits derive from suppressing production of androgens, which prostate cells need to thrive. Estrogens suppress androgen production by acting in the pituitary to suppress release of ICSH; in the absence of ICSH, production of androgens by the testes declines. Adverse effects of estrogens include nausea, fluid retention, hypercalcemia, depression, thromboembolic disorders, and gynecomastia. The basic pharmacology of the estrogens is discussed in [Chapter 60](#).

103.2.4.2 Ketoconazole

Ketoconazole [Nizoral], used primarily for fungal infections (see [Chapter 91](#)), can also be used for prostate cancer. Benefits derive from inhibiting testicular and adrenal production of androgens, and from direct toxicity to prostate cells. The drug is employed as secondary therapy in men who have rising prostate-specific antigen levels despite treatment with a GnRH agonist plus an antiandrogen. Dosages are higher than those used for antifungal therapy (400 mg 3 times a day compared with 200 mg once a day), and hence side effects are common. Among these are nausea, vomiting, fatigue, skin changes, liver damage, and gynecomastia. Because high-dose ketoconazole can suppress adrenal production of glucocorticoids, the drug is usually combined with hydrocortisone.

103.2.4.3 Estramustine

Estramustine [Emcyt] is a hybrid molecule composed of estradiol (an estrogen) coupled to nitrogen mustard (an alkylating agent; see [Chapter 101](#)). The only indication for the drug is palliative therapy of *advanced prostate cancer*. Following oral administration, estramustine

becomes concentrated in prostate cells, apparently through the actions of a unique “estramustinebinding protein.” Injury to prostate cells appears to result from three mechanisms. First, estramustine acts as a weak alkylating agent. Second, hydrolysis of estramustine releases free estradiol, which suppresses ICSH release by the pituitary, thereby depriving prostate cells of hormonal support. Third, and most importantly, the drug binds to microtubules of mitotic spindles, and thereby disrupts mitosis. As a result, estramustine has M-phase specificity.

Adverse effects are caused primarily by free estradiol. Gynecomastia is common. The most serious effect is thrombosis, with resultant myocardial infarction and stroke. Other adverse effects include fluid retention, nausea, vomiting, diarrhea, and hypercalcemia.

103.2.4.4 Cytotoxic Anticancer Drugs

Cytotoxic agents are used for hormone-refractory prostate cancer. Effective drugs include docetaxel, paclitaxel, and mitoxantrone. Docetaxel (combined with prednisone) can prolong survival, and hence is considered a treatment of choice. Mitoxantrone plus prednisone can provide palliation, and is a reasonable option for patients who cannot tolerate docetaxel. The pharmacology of these cytotoxic drugs is discussed in [Chapter 101](#).

10... DRUGS FOR BREAST CANCER

Breast cancer is the most common cancer affecting women in the United States. In 2008, an estimated 184,450 new cases were diagnosed, and 40,930 were fatal. Because of early detection and improvements in treatment, the death rate for breast cancer is declining.

Principal treatment modalities are *surgery, radiation, cytotoxic drugs (chemotherapy), and hormonal drugs*. Surgery and radiation are considered primary therapy; chemotherapy and hormonal therapy are used as adjuvants. For a woman with early breast cancer, treatment typically consists of surgery (using total mastectomy or partial mastectomy [lumpectomy]) followed by local radiation. After that, chemotherapy is used to kill cells left behind after surgery and radiation, and to kill cells that may have metastasized to other sites. Finally, hormonal agents are taken for several years to reduce recurrence. Increasingly, chemotherapy is used *before* surgery—so-called neoadjuvant therapy—to shrink large tumors, and thereby permit lumpectomy in women who would otherwise require mastectomy.

Hormonal agents for breast cancer fall into two major groups: *antiestrogens* (eg, tamoxifen [Nolvadex]) and *aromatase inhibitors* (eg, anastrozole [Arimidex]). Antiestrogens block receptors for estrogen, whereas aromatase inhibitors block estrogen production. In both cases, tumor cells are

deprived of the estrogen they need in order to grow. However, there is a caveat: For these drugs to work, tumor cells must have estrogen receptors (ERs). Fortunately, the majority of breast cancers are ER positive. For years, tamoxifen had been the hormonal agent of choice. However, recent data have shown that, in postmenopausal patients, aromatase inhibitors are more effective, both in the metastatic and adjuvant setting. There is a wealth of data showing that adjuvant hormonal therapy can reduce tumor recurrence and prolong life.

In addition to chemotherapy and hormonal therapy, there are two other drugs—*trastuzumab* [Herceptin] and *lapatinib* [Tykerb]—that can be used for adjuvant treatment. Trastuzumab blocks receptors known as HER2 (see below), and lapatinib inhibits two enzymes, known as HER2 tyrosine kinase and EGFR tyrosine kinase (see below). Both drugs are indicated only for cancers that are HER2 positive.

What about breast cancer *prevention*? One drug—tamoxifen—is approved for preventing breast cancer in women at high risk. Tamoxifen decreases the risk of breast cancer by 40% to 50%, but carries a small but serious risk of endometrial cancer and thrombosis. Nonetheless, in women at high risk for breast cancer, the benefits of tamoxifen outweigh the risks.

Drugs for adjuvant therapy of breast cancer are summarized in [Table 102-2](#).

1200

TABLE 102-2 Drugs for Adjuvant Therapy of Breast Cancer

Drug Class	Example	Mechanism	Indications	Major Adverse Effects
Antiestrogens	Tamoxifen [Nolvadex]	Blockade of estrogen receptors	ER-positive breast cancer in pre- and postmenopausal women	Increased risk of endometrial cancer and thrombosis Hot flushes, fluid retention, vaginal discharge, nausea, vomiting, and menstrual irregularities
Aromatase inhibitors	Anastrozole [Arimidex]	Inhibition of estrogen synthesis	ER-positive breast cancer in postmenopausal women only	Increased risk of osteoporosis and fractures, myalgias and arthralgias
Anti-HER2 antibody	Trastuzumab [Herceptin]	Blockade of HER2 receptors	HER2-positive breast cancer in pre- and postmenopausal women	Cardiotoxicity and hypersensitivity reactions
Cytotoxic drugs	Doxorubicin [Adriamycin] + cyclophosphamide [Cytoxan, Neosar]	Direct cell kill by DNA intercalation, topoisomerase II inhibition, and DNA alkylation	Breast cancer in all women, regardless of ER, HER2, or menopausal status	Together, these drugs can cause cardiotoxicity, bone marrow suppression, alopecia, oral and GI ulceration, and hemorrhagic cystitis
	Paclitaxel [Taxol, Onxol, Abraxane]	Direct cell kill by mitotic arrest	See doxorubicin + cyclophosphamide	Bone marrow suppression, peripheral neuropathy, alopecia, cardiotoxicity, muscle and joint pain Severe hypersensitivity reactions with Taxol and Onxol, but not Abraxane
ER = estrogen receptor, HER2 = human epidermal growth factor receptor 2.				

103.3.1 Antiestrogens

Antiestrogens are drugs that block estrogen receptors, and hence only work against cells that are ER positive. Benefits derive from depriving tumor cells of the growth-promoting influence of estrogen.

Currently, four antiestrogens are available. Of these, only one—fulvestrant—is a *pure* estrogen receptor antagonist. The other three—tamoxifen, toremifene, and raloxifene—have *mixed* effects on estrogen receptors, causing receptor blockade in some tissues and receptor activation in others. Because they exert both estrogenic and antiestrogenic actions, these three drugs have been labeled *selective estrogen receptor modulators*, or *SERMs*—a term we first encountered in [Chapter 60](#) (Estrogens and Progestins). Hence, although we refer to these drugs as *antiestrogens* when discussing their use in cancer, keep in mind that they can activate estrogen receptors as well as block them. Whether estrogen receptors in a particular tissue will be activated or blocked depends on the SERM being used.

103.3.1.1 Tamoxifen

Tamoxifen [Nolvadex] is a commonly prescribed drug for breast cancer. This agent is approved for treating established disease and for reducing the occurrence of breast cancer in women at high risk. As noted, tamoxifen is a SERM, not a pure estrogen receptor antagonist.

103.3.1.1.1 Overview of Actions.

Like other SERMs, tamoxifen blocks estrogen receptors in some tissues and activates them in others. Receptor *blockade* underlies the drug's utility against breast cancer. Receptor *activation* leads to other beneficial effects (increased bone mineral density, reduction of low-density-lipoprotein cholesterol, elevation of high-density lipoprotein cholesterol) as well as to adverse effects (endometrial cancer and blood clots).

103.3.1.1.2 Mechanism of Action in Breast Cancer.

Tamoxifen blocks estrogen receptors on breast cancer cells, and thereby prevents receptor activation by estradiol, the principal endogenous estrogen. Estrogen acts on tumor cells to stimulate growth and proliferation. Hence, in the absence of estradiol's influence, the rate of tumor cell proliferation declines. Tumors regress in size as the rate of cell death outpaces

new cell production. Obviously, if tamoxifen is to be effective, target cells must be ER positive.

103.3.1.1.3 Use for Treatment of Breast Cancer.

Tamoxifen has two treatment applications: (1) as adjuvant therapy to suppress growth of residual cancer cells following surgery, and (2) treatment of metastatic disease. Efficacy as adjuvant therapy has been evaluated in 55 randomized trials involving more than 37,000 women. The result? Treatment for 1, 2, and 5 years decreased tumor recurrence by 21%, 29%, and 47%, respectively. Benefits were limited almost entirely to women with ER-positive cancer. Tamoxifen can be used in both premenopausal and postmenopausal women.

103.3.1.1.4 Use for Prevention of Breast Cancer.

Tamoxifen is approved for reducing the development of breast cancer in healthy women at high risk. Approval was based on results of the Breast Cancer Prevention Trial, which enrolled 13,388 otherwise healthy women who had risk factors for breast cancer (eg, age older than 60, family history of breast cancer, failure to give birth before age 30, a breast biopsy showing atypical hyperplasia). Half of the participants received tamoxifen (20 mg PO daily) and half received placebo. After an average follow-up time of 4 years, daily tamoxifen reduced the incidence of breast cancer by 44%. Unfortunately, tamoxifen *increased* the incidence of endometrial cancer, pulmonary embolism, and deep vein thrombosis. Hence, women considering tamoxifen for chemoprevention must carefully weigh the benefits of treatment (reduced risk of breast cancer) against the risks (increased risk of endometrial cancer and thromboembolic events). According to guidelines issued in 2002 by the U.S. Preventive Services Task Force (USPSTF), tamoxifen chemoprevention is appropriate only for women at *high* risk, and not for women at lower risk. Specific recommendations for high-risk women in different age groups are as follows:

- *Age 40 through 49*—Tamoxifen is a good choice, except for women at risk for thrombosis.
- *Age 50 through 59*—Tamoxifen is a good choice, except for women at risk for thrombosis and for women who still have a uterus (the risk of endometrial cancer is higher for women over 50).
- *Age 60 and above*—Tamoxifen is not recommended (although older women have the highest risk for breast cancer, they also have the highest risk for complications from

postmenopausal women, endometrial cancer is usually caught early, due to abnormal menstrual bleeding.

103.3.1.1.8 Dosage and Administration.

The usual dosage for adjuvant *treatment* of breast cancer is 20 mg PO once a day. Larger doses do not increase benefits. In most cases, treatment should continue 5 years. The dosage for *prevention* of breast cancer in high-risk women is 20 mg PO daily for 5 years. There are no data to indicate that extending treatment beyond 5 years increases benefits.

103.3.1.2 Toremifene

103.3.1.2.1 Actions and Use.

Toremifene [Fareston] is a SERM indicated for metastatic *breast cancer* in postmenopausal women with ER-positive tumors or tumors for which ER status is unknown. The drug is a structural analog of tamoxifen, and shares most of that drug's properties. Like tamoxifen, toremifene has antiestrogenic actions in some tissues, and estrogenic actions in others. In women with breast cancer, toremifene blocks estrogen receptors on tumor cells, thereby depriving them of estrogen's growth-promoting effects. In clinical trials, toremifene was about as effective as tamoxifen: With both drugs, the response rate in metastatic disease was about 20%, and median survival time was about 30 months. In a crossover study, most patients who failed to respond to tamoxifen also failed to respond to toremifene. The recommended dosage is 60 mg PO once a day.

103.3.1.2.2 Pharmacokinetics.

Toremifene is well absorbed following oral administration. Plasma levels peak in 3 hours. The drug undergoes extensive hepatic metabolism, primarily by CYP3A4. Metabolites are excreted in the feces. The half-life is prolonged (about 5 days) owing to enterohepatic recirculation. As with tamoxifen, drugs that induce CYP3A4 will reduce toremifene levels, and drugs that inhibit the enzyme will raise toremifene levels.

103.3.1.2.3 Adverse Effects.

Adverse effects are like those of tamoxifen. Hot flushes are most common, occurring in 35% of those treated. Other common reactions are sweating (20%), nausea (14%), and vaginal discharge (13%). Patients may also experience dizziness (9%), vomiting (4%), and vaginal

bleeding (2%). Hypercalcemia may occur in women with bone metastases. There is a small risk of thromboembolic events. Cataracts and elevation of liver enzymes have been reported.

Like tamoxifen, toremifene *activates* estrogen receptors in the uterus. As a result, the drug can promote uterine hyperplasia and uterine cancer.

103.3.1.3 Raloxifene

Raloxifene [Evista] is a SERM with actions similar to those of tamoxifen, but with a lower risk of uterine cancer and thromboembolism. Preliminary results of the Study of Tamoxifen and Raloxifene (STAR), released in April 2006, indicate that, in women at high risk, raloxifene and tamoxifen are equally good at reducing breast cancer occurrence. Moreover, raloxifene was safer, causing 36% fewer cases of uterine cancer and 30% fewer cases of blood clots. The basic pharmacology of raloxifene and its use in osteoporosis are discussed in [Chapter 74](#).

103.3.1.4 Fulvestrant

103.3.1.4.1 Actions, Use, and Dosage.

Fulvestrant [Faslodex], an antiestrogen approved in 2002, is indicated for metastatic ER-positive *breast cancer* in postmenopausal women. Unlike tamoxifen and other SERMs, which block some estrogen receptors and activate others, fulvestrant is a *pure estrogen receptor antagonist*—the first one available. As with other antiestrogens, benefits derive from depriving breast cancer cells of required hormonal stimulation. Fulvestrant is administered IM in the buttock. Dosage is 250 mg once a month, given either as one 5-mL injection or two 2.5-mL injections.

103.3.1.4.2 Clinical Trials.

In two trials, fulvestrant was compared with anastrozole, an aromatase inhibitor (see below).
The study enrolled postmenopausal women with locally advanced or metastatic breast cancer that had progressed despite hormonal therapy. The result? Both fulvestrant and anastrozole were equally effective with respect to objective tumor response rates and median time to disease progression. However, response duration was greater with fulvestrant (16.7 months vs. 13.6 months). At this time, there are no data on how fulvestrant compares directly with tamoxifen.

1202

1203

103.3.1.4.3 Pharmacokinetics.

Plasma levels peak about 7 days after IM injection, and remain therapeutic for at least 1 month. Steady-state levels are reached after three to six monthly doses. The drug undergoes hepatic metabolism followed by renal excretion. The apparent half-life is 40 days.

103.3.1.4.4 Adverse Effects and Drug Interactions.

Fulvestrant is generally well tolerated. The most common adverse effects are GI disturbances, hot flushes, headache, pharyngitis, and bone and back pain. Thromboembolism can occur but is uncommon. In contrast to SERMs, fulvestrant poses no risk of endometrial cancer. In clinical trials, injection-site reactions (inflammation; mild, transient pain) developed in 7% of women receiving a single 5-mL injection and in 27% of women receiving two 2.5-mL injections. Fulvestrant has no known drug interactions.

103.3.2 Aromatase Inhibitors

The aromatase inhibitors are used to treat ER-positive breast cancer in *postmenopausal* women. These drugs block the production of estrogen from androgenic precursors, and thereby deprive breast cancer cells of the estrogen they need for growth. Aromatase inhibitors do not block production of estrogen by the ovaries, and hence are of little benefit in premenopausal women. In fact, aromatase inhibitors will cause a compensatory rise in estradiol in premenopausal patients. Aromatase inhibitors are more effective than tamoxifen and have a different toxicity profile. Unlike tamoxifen, aromatase inhibitors pose no risk of endometrial cancer and only rarely cause thromboembolism. However, they *can* increase the risk of fractures and have been associated with moderate to severe myalgias.

103.3.2.1 Anastrozole

103.3.2.1.1 Mechanism and Use.

Anastrozole [Arimidex] is approved for first-line oral therapy of *postmenopausal* women with early or advanced *ER-positive breast cancer*. The drug works by depriving breast cancer cells of estrogen. In postmenopausal women, the major source of estrogen is adrenal androgens, which are converted into estrogen by the enzyme *aromatase* in peripheral tissues. Anastrozole inhibits aromatase, and thereby reduces estrogen production. With regular use, the drug lowers estrogen to undetectable levels. In women with estrogen-dependent cancer,

estrogen deprivation can arrest tumor growth, and may cause outright cell death. In clinical trials, anastrozole was not effective in women with ER-negative tumors or in women who did not respond initially to tamoxifen. The recommended dosage is 1 mg PO once a day. The appropriate duration of treatment is under study. Anastrozole may be used as initial therapy, or as a follow-up to therapy with tamoxifen.

103.3.2.1.2 Adverse Effects.

Anastrozole is generally well tolerated. In clinical trials, only 3.3% of patients withdrew because of adverse effects. At a dose of 1 mg, the most common adverse effects are asthenia (16%), nausea (16%), headache (13%), and hot flushes (12%). Other reactions include anorexia, vomiting, diarrhea, constipation, dyspnea, peripheral edema, vaginal hemorrhage, hypertension, and pain (including bone, back, pelvic, and abdominal pain).

About 25% of women experience joint and musculoskeletal pain. The cause may be estrogen deprivation. Persistent or severe pain drives about 5% of users to discontinue treatment. For women who choose to continue anastrozole, pain can often be managed with a mild analgesic (eg, acetaminophen, ibuprofen).

Estrogen depletion increases the risk of *osteoporosis*. To reduce bone loss, women should ensure adequate intake of calcium and vitamin D. Women at high risk should take a bisphosphonate (eg, alendronate [Fosamax]).

103.3.2.1.3 Comparison with Tamoxifen.

As shown in the *Arimidex, Tamoxifen, Alone or in Combination* (ATAC) trial, which enrolled postmenopausal women with early breast cancer, anastrozole is more effective than tamoxifen and causes fewer adverse effects. After a median follow-up of 5.6 years, cancer recurred in 13% fewer of the women who took anastrozole, and the time to cancer recurrence was longer. Regarding side effects, anastrozole is less likely to cause hot flushes, weight gain, or vaginal bleeding—although it may cause more nausea and irritability. In contrast to tamoxifen, anastrozole is devoid of all estrogenic activity, and hence does not promote endometrial cancer or thromboembolic events—although it does increase the risk of fractures. Because of their efficacy and tolerability, aromatase inhibitors have replaced tamoxifen as the drug of first choice for treating ER-positive breast cancer in postmenopausal women.

103.3.2.2 Letrozole

Letrozole [Femara], a selective aromatase inhibitor, is indicated for (1) first-line therapy of early and advanced *ER-positive breast cancer* in postmenopausal women, and (2) extended adjuvant therapy of early breast cancer following 5 years of adjuvant therapy with tamoxifen. Like anastrozole, letrozole blocks conversion of androgens into estrogens, and thereby deprives breast cancer cells of estrogen's growth-promoting influence. In one study of women with advanced breast cancer, letrozole (2.5 mg/day) was more effective than tamoxifen (20 mg/day): the objective response rate with letrozole was higher (30% vs. 20%) and the time to tumor progression was longer (9.4 months vs. 6 months). In women with early breast cancer who had received 5 years of tamoxifen therapy, following with letrozole reduces the risk of recurrence. Letrozole's most common adverse effects are musculoskeletal pain (21%) and nausea (13%). Reactions that occur in 6% to 9% of patients include headache, arthralgia, fatigue, constipation, dyspnea, cough, vomiting, diarrhea, and hot flushes. Extremely low doses are embryotoxic and fetotoxic in animals. Like anastrozole, and unlike tamoxifen, letrozole poses no risk of endometrial cancer. However, it can cause osteoporosis and fractures, and, rarely, thromboembolism. No significant drug interactions have been reported.

103.3.2.3 Exemestane

Exemestane [Aromasin] is indicated for oral therapy of (1) *advanced ER-positive breast cancer* in postmenopausal women whose disease has progressed despite treatment with tamoxifen, and (2) *early ER-positive breast cancer* in postmenopausal women who have received 2 to 3 years of tamoxifen therapy and then are switched to adjuvant exemestane to complete a 5-year course of treatment. Like anastrozole, exemestane inhibits aromatase, and thereby reduces estrogen levels. A dosage of 25 mg once daily (administered after a meal) reduces circulating estrogen by 85% to 95%. In the absence of sufficient estrogen, estrogen-dependent tumors cannot thrive. In clinical trials, the objective response rate was about 25%.

Exemestane is rapidly absorbed following oral administration. The drug is widely distributed and cleared by extensive metabolism. Excretion is in the urine and feces. Its half-life is about 24 hours.

Exemestane is generally well tolerated. The most common adverse effects are fatigue (22%), nausea (18%), hot flushes (13%), depression (13%), and weight gain (8%). Like anastrozole

and letrozole, exemestane may cause musculoskeletal pain. Increased risk of osteoporosis and fractures is a concern. Exemestane appears devoid of significant drug interactions.

1203

103.3.3 Trastuzumab

1204

103.3.3.1 Actions and Use.

Trastuzumab [Herceptin] is a monoclonal antibody indicated for intravenous therapy of metastatic *breast cancer*. All patients must have tumors that overexpress *human epidermal growth factor receptor 2* (HER2), a transmembrane receptor that helps regulate cell growth. Trastuzumab binds with HER2 and thereby (1) inhibits cell proliferation and (2) promotes antibody-dependent cell death. Between 25% and 30% of metastatic breast cancers produce excessive HER2. High numbers of HER2 receptors are associated with unusually aggressive tumor growth. For treatment of breast cancer, trastuzumab may be used (1) alone in women who failed to respond to prior chemotherapy, (2) in combination with paclitaxel as first-line therapy, and (3) for adjuvant treatment as part of a regimen containing doxorubicin, cyclophosphamide, and paclitaxel.

103.3.3.2 Clinical Trials.

In one trial involving women with metastatic disease, treatment with trastuzumab alone produced a complete response in 3% of patients, and a partial response (more than 50% tumor regression) in 14% of patients. In a trial reported in 2005, chemotherapy alone—doxorubicin plus cyclophosphamide, followed by paclitaxel—was compared with chemotherapy plus trastuzumab. The result? Adding trastuzumab to the regimen produced a significant increase in 3-year disease-free survival (87% vs. 75% with chemotherapy alone), and also produced a significant reduction in 3-year mortality. These data suggest that trastuzumab should be considered for most women who have HER2-positive disease.

103.3.3.3 Adverse Effects.

The principal concern with trastuzumab is *cardiotoxicity*, manifesting as ventricular dysfunction and congestive heart failure. In clinical trials, the incidence of symptomatic heart failure was 7% with trastuzumab alone, and 28% when trastuzumab was combined with doxorubicin, a drug with prominent cardiotoxic actions. Combining trastuzumab with paclitaxel can also result in cardiac damage. Because of its cardiotoxicity, trastuzumab should be used with caution in women with pre-existing heart disease. Combined use with

doxorubicin and other anthracyclines should generally be avoided. Many patients experience a flu-like syndrome, which also occurs with other monoclonal antibodies. Symptoms include chills, fever, pain, weakness, nausea, vomiting, and headache. The syndrome develops in 40% of patients receiving their first infusion, and then diminishes with subsequent infusions. In contrast to cytotoxic anticancer drugs, trastuzumab does not cause bone marrow suppression or alopecia.

Postmarketing reports indicate that trastuzumab can cause potentially fatal hypersensitivity reactions, infusion reactions, and pulmonary events. Symptoms include urticaria, bronchospasm, angioedema, hypotension, dyspnea, wheezing, pleural effusions, pulmonary edema, and hypoxia requiring oxygen. Most severe reactions developed in association with the first dose, either during the infusion or by 12 hours after. If symptoms develop during the infusion, the infusion should be stopped. Death has occurred primarily in patients with pre-existing pulmonary disorders. Accordingly, patients with compromised pulmonary function should be managed with extreme caution.

103.3.3.4 Dosage and Administration.

Treatment consists of a loading dose (4 mg/kg infused over 90 minutes) followed by weekly maintenance doses (2 mg/kg infused over 30 minutes). An alternative regimen uses a larger loading dose (8 mg/kg), and larger but less frequent maintenance doses (6 mg/kg every 3 weeks).

103.3.4 Lapatinib

103.3.4.1 Actions and Use.

Lapatinib [Tykerb] is an oral inhibitor of two enzymes—HER2 tyrosine kinase and epidermal growth factor receptor (EGFR)—tyrosine kinase—that are involved in cell signal transduction. Inhibition of these enzymes results in apoptosis and suppression of tumor cell growth. Lapatinib, in combination with capecitabine (see [Chapter 101](#)), is approved for treating HER2-positive breast cancer, but only in patients who have received prior therapy with multiple drugs, including an anthracycline, a taxane, and trastuzumab. EGFR-tyrosine kinase is discussed further below under *EGFR-Tyrosine Kinase Inhibitors*.

103.3.4.2 Adverse Effects.

The most common adverse effects of lapatinib plus capecitabine are GI disturbances (diarrhea, nausea, vomiting), fatigue, anemia, liver toxicity, and skin reactions (rash and palmar-plantar erythrodysesthesia [swelling and numbness of the hands and feet]). Diarrhea occurs in 65% of patients, and is the most common reason for stopping treatment. Like other HER2 inhibitors, lapatinib may pose a risk of cardiotoxicity. Accordingly, the drug should be used with caution in patients with existing cardiac impairment.

103.3.4.3 Drug Interactions.

Lapatinib is metabolized by CYP3A4, and hence CYP3A4 inducers (eg, phenytoin, carbamazepine, rifampin, rifabutin, phenobarbital, St. John's wort) can lower lapatinib levels, and CYP3A4 inhibitors (eg, ketoconazole, itraconazole, erythromycin, indinavir, nelfinavir) can raise lapatinib levels. If possible, CYP3A4 inducers and inhibitors should be avoided.

103.3.4.4 Preparations, Dosage, and Administration.

Lapatinib [Tykerb] is supplied in 250-mg tablets for oral dosing. The recommended dosage is 1250 mg once daily, administered 1 hour before or 2 hours after a meal. The regimen consists of lapatinib plus capecitabine (2000 mg/m² once daily), taken on days 1 through 14 of a repeating 21-day cycle.

103.3.5 Cytotoxic Drugs (Chemotherapy)

Cytotoxic drugs may be used before breast surgery or after. When used before surgery, chemotherapy can shrink large tumors, thereby permitting lumpectomy in women who would otherwise require a mastectomy. When used after surgery, chemotherapy can kill cancer cells that remain in the breast, as well as cells that may have metastasized to distant sites. A common regimen for breast cancer consists of doxorubicin (an anthracycline-type anticancer antibiotic) plus cyclophosphamide (an alkylating agent) followed by paclitaxel (a mitotic inhibitor). The pharmacology of these cytotoxic drugs is discussed in [Chapter 101](#).

^{10...} BIOLOGIC RESPONSE MODIFIERS: IMMUNOSTIMULANTS

Biologic response modifiers are drugs that alter host responses to cancer. Many of these drugs are immunostimulants, others render cancer cells nonmalignant by causing them to differentiate into

nonproliferative forms, and others (hematopoietic growth factors) enable the host to better tolerate the myelosuppressive actions of anticancer drugs (see [Chapter 55](#)). In this chapter, all of the biologic response modifiers discussed are immunostimulants. Their trade names, indications, and routes are summarized in [Table 102-3](#).

103.4.1 Interferon Alfa-2a and Interferon Alfa-2b

Interferons are naturally occurring proteins with complex antiviral, anticancer, and immunomodulatory actions. Release of endogenous interferons is triggered by viral infections and other stimuli. Interferons are active against a variety of solid tumors and hematologic malignancies. They are also active against hepatitis B and hepatitis C (see [Chapter 92](#)). Forms of interferon beta are used for multiple sclerosis (see [Chapter 23](#)).

103.4.1.1 Description.

Interferon alfa-2a [Roferon-A] and interferon alfa-2b [Intron A] are glycoproteins that contain 165 amino acids. The two drugs, referred to collectively as interferon alfa, are identical except for one amino acid. Commercial production is by recombinant DNA technology.

TABLE 102-3 Biologic Response Modifiers: Immunostimulants

Generic Name	Trade Name	Route	Indications
Interferon alfa-2a	Roferon-A	IM, IV, subQ	Hairy cell leukemia, chronic myelogenous leukemia, malignant melanoma, follicular lymphoma, AIDS-related Kaposi's sarcoma*
Interferon alfa-2b	Intron A		
Aldesleukin (interleukin-2)	Proleukin	IV	Metastatic renal cell cancer, metastatic melanoma
BCG vaccine	TheraCys, TICE BCG, Pacis	Intravesical	<i>In situ</i> bladder cancer

* In addition to these approved indications, interferons have been used to treat many other cancers, including acute leukemias and cancers of the bladder, ovary, and kidney.

103.4.1.2 Mechanism of Action.

Anticancer effects are thought to result from two basic processes: (1) enhancement of host immune responses and (2) direct antiproliferative effects on cancer cells. Both processes are mediated by binding of interferons to cell-surface receptors, with resultant increased expression of certain genes and reduced expression of others. Interferons can cause G₀ cells to remain dormant, thereby preventing proliferation. In addition, interferons can cause proliferating cells to differentiate into nonproliferative mature forms.

103.4.1.3 Antineoplastic Uses.

Interferons alfa-2a and alfa-2b are approved for *hairy cell leukemia, chronic myelogenous leukemia, malignant melanoma, follicular lymphoma, and AIDS-related Kaposi's sarcoma*. Investigational uses include *acute leukemias and cancers of the bladder, ovary, and kidney*. Response rates are generally higher with hematologic cancers than with solid tumors.

103.4.1.4 Pharmacokinetics.

Interferon alfa is administered by IM or subQ injection. Plasma levels peak in 4 to 8 hours. Inactivation occurs rapidly in body fluids and tissues. No intact drug appears in the urine.

103.4.1.5 Adverse Effects.

Interferon alfa causes multiple adverse effects. The most common is a flu-like syndrome characterized by fever, fatigue, myalgia, headache, and chills. Symptoms tend to diminish with continued therapy. Some symptoms (fever, headache, myalgia) can be reduced with acetaminophen. Other common effects include anorexia, weight loss, diarrhea, abdominal pain, dizziness, and cough. Prolonged or high-dose therapy can cause bone marrow suppression, thyroid dysfunction, alopecia, cardiotoxicity, and neurotoxicity, which can cause profound fatigue and depression.

103.4.2 Aldesleukin (Interleukin-2)

Aldesleukin [Proleukin], also known as interleukin-2 (IL-2), is an immuno-stimulant indicated for advanced renal carcinoma and melanoma. Because severe adverse effects occur often, the drug must be administered in a hospital that has an intensive care facility; a specialist in cardiopulmonary or intensive care medicine must be available.

103.4.2.1 Description and Actions.

Aldesleukin is a large glycoprotein nearly identical in structure and actions to human IL-2. The drug is produced by recombinant DNA technology. Like IL-2, aldesleukin stimulates immune function. Specific responses include enhanced production and cytotoxicity of lymphocytes; increased production of interleukin-1, interferon gamma, and tumor necrosis factor; and induction of lymphokine-activated killer cell activity. These powerful immunostimulant actions are believed to underlie antitumor effects.

103.4.2.2 Therapeutic Use.

Aldesleukin has two approved uses: *metastatic renal cell carcinoma* and *metastatic melanoma*. Among patients with renal cell cancer, 4% respond completely and 11% respond partially. The median response duration is 2 years.

103.4.2.3 Pharmacokinetics.

Aldesleukin is administered by IV infusion and distributes throughout the extracellular space. About 70% of each dose undergoes preferential uptake by the liver, kidneys, and lungs. Renal enzymes convert the drug into inactive metabolites, which are excreted in the urine. The drug's half-life is short—just 85 minutes.

103.4.2.4 Adverse Effects.

Practically all patients experience significant toxicity. The fatality rate is high (4%). Effects seen most frequently are fever and chills (89%), nausea and vomiting (87%), hypotension (85%), anemia (77%), diarrhea (76%), altered mental status (76%), sinus tachycardia (70%), impaired renal function (61%), impaired liver function (56%), pulmonary congestion (54%), dyspnea (52%), and pruritus (48%). Depression may also occur.

Capillary leak syndrome (CLS) is of particular concern. This potentially fatal reaction is characterized by hypotension and reduced organ perfusion (secondary to loss of vascular tone and extravasation of plasma proteins and fluid). Symptoms begin to develop immediately after treatment. CLS may be associated with angina pectoris, cardiac dysrhythmias, myocardial infarction, pronounced respiratory insufficiency, renal insufficiency, GI bleeding, and altered mental status. Because of the risk of CLS, aldesleukin must not be given to patients with

cardiac, pulmonary, renal, hepatic, or central nervous system CNS impairment. Careful monitoring is essential.

103.4.3 BCG Vaccine

103.4.3.1 Description and Therapeutic Use.

BCG vaccine [TheraCys, TICE BCG, Pacis] is a freeze-dried preparation of attenuated *Mycobacterium bovis* (bacillus of Calmette and Guérin). The vaccine is approved for primary and relapsed *carcinoma in situ of the bladder*, both in the presence and absence of associated papillary tumors. However, the vaccine should not be used for papillary tumors alone. To treat bladder cancers, BCG vaccine is administered intravesically (ie, directly into the bladder through a urethral catheter). In addition to its use in cancer therapy, BCG vaccine is used to protect against tuberculosis (see [Chapter 89](#)).

103.4.3.2 Mechanism of Action.

BCG vaccine is a nonspecific immunostimulant. Instillation in the bladder produces a local inflammatory response that, by an unknown mechanism, promotes regression of tumors in the urothelial lining.

103.4.3.3 Adverse Effects.

The most common adverse effects, which result from bladder irritation, are dysuria, urinary frequency, urinary urgency, and hematuria. Urinary status should be monitored closely. The most common systemic reactions are malaise, fatigue, fever, and chills.

Because BCG vaccine consists of live *M. bovis*, therapy carries a risk of systemic infection, including fatal septic shock. Accordingly, the vaccine is contraindicated for (1) immunocompromised patients (eg, those taking immunosuppressant drugs, those with symptomatic or asymptomatic HIV infection); (2) patients with fever of unknown origin (because it may signify infection); and (3) patients with urinary tract infections (because there is an increased risk of systemic absorption of BCG vaccine).

Because BCG vaccine is infectious, it must be handled using aseptic technique. All materials employed during administration should be disposed of in plastic bags labeled “Infectious Waste.” Urine voided within 6 hours of BCG instillation should be disinfected with an equal volume of 5% hypochlorite before flushing.

1205

10... TARGETED DRUGS

Targeted anticancer drugs are designed to bind with specific molecules (targets) that drive tumor growth. The hope is that these drugs will be more selective than hormones and cytotoxic anticancer drugs, and hence will be able to destroy cancer cells while leaving normal cells untouched. A few targeted drugs, such as imatinib [Gleevec], have been remarkably successful, producing complete responses with relatively mild adverse effects. Unfortunately, with many other targeted drugs, responses have been less impressive, while adverse effects have been more severe. Nonetheless, the concept of targeted therapy has great appeal, and intensive research is underway to make it more of a reality.

How do targeted drugs work? Many of these drugs are antibodies that bind with specific antigens on tumor cells; others are small molecules that inhibit intracellular enzymes. Some antibodies mark cancer cells for immune attack, some block cell-surface receptors, some deliver toxic drugs or radioactivity, and some inhibit angiogenesis, and thereby deprive tumor cells of their blood supply. Most of the small molecules in current use inhibit specific tyrosine kinases, and thereby disrupt intracellular signaling pathways. Properties of the targeted drugs are summarized in [Table 102-4](#).

103.5.1 EGFR-Tyrosine Kinase Inhibitors

The *epidermal growth factor receptor* (EGFR) is a transmembrane regulatory molecule that works through activation of intracellular tyrosine kinase (TK). The receptor portion of EGFR, which is found on the outer surface of the cell membrane, is coupled with TK on the inner surface of the cell membrane. Binding of an agonist to EGFR activates TK, which in turn activates signaling pathways that regulate cell proliferation and survival. EGFRs are expressed constitutively in many normal epithelial tissues (eg, skin, hair follicles) and are overexpressed in several cancers, including cancers of the lung, breast, prostate, bladder, ovary, colon, and rectum. Overexpression is associated with unregulated cell growth and poor prognosis. Drugs that inhibit EGFR suppress cell proliferation and promote apoptosis (programmed cell death). At this time, we have five EGFR-TK inhibitors. Two of these drugs—cetuximab and panitumumab—are monoclonal antibodies that bind with the receptor portion of EGFR-TK, and thereby prevent its activation by agonists. The other three drugs—erlotinib, gefitinib, and lapatinib—are small molecules that work inside the cell to inhibit TK directly. It should be noted that EGFRs belong to the same receptor family as HER2 (human epidermal growth factor receptor 2), the target that trastuzumab [Herceptin] works through.

103.5.1.1 Cetuximab

Cetuximab [Erbix] is a monoclonal antibody with a novel mechanism of action: blockade of EGFRs. The drug is approved for refractory colorectal cancer and for carcinoma of the head and neck. Infusion reactions, acneform rash, low magnesium, and GI symptoms are common.

103.5.1.1.1 Mechanism of Action.

Cetuximab acts as a competitive antagonist at EGFRs. As noted, these receptors, which help regulate cell growth, are overexpressed in certain cancers, including those of the colon and rectum. EGFR blockade inhibits cell growth and promotes apoptosis. In animal studies, cetuximab decreased growth and survival of cancer cells that overexpress EGFR, but had no effect on cancer cells that lack EGFR.

103.5.1.1.2 Therapeutic Uses.

103.5.1.1.2.1 Colorectal Cancer.

Cetuximab is approved for metastatic, EGFR-positive colorectal cancer. The drug may be added to an irinotecan-based regimen (if the cancer has progressed despite irinotecan treatment), or it may be used alone (in patients who cannot tolerate irinotecan). In clinical trials, cetuximab delayed tumor growth and promoted tumor regression. However, we don't yet know if it prolongs survival.

103.5.1.1.2.2 Other Cancers.

Cetuximab, in combination with radiation, is approved for initial treatment of locally or regionally advanced *carcinoma of the head and neck*. The drug is under investigation for use against other cancers that express EGFR, including cancers of the lung, breast, and pancreas.

103.5.1.1.3 Adverse Effects.

Cetuximab causes adverse effects in most patients. The effects of greatest concern are severe infusion reactions, severe rash, and interstitial lung disease.

Severe *infusion reactions*—characterized by rapid-onset airway obstruction, hypotension, and urticaria—develop in 3% of patients. One fatality has been reported. Severe reactions

can happen with any infusion, but most (90%) occur with the first infusion. If a severe reaction develops, cetuximab should be discontinued immediately and never used again. Agents for medical management—epinephrine, glucocorticoids, IV antihistamines, bronchodilators, and oxygen—should always be on hand. To reduce the risk of a severe reaction, premedication with an IV antihistamine (eg, 50 mg diphenhydramine) is recommended.

Acne-like rash, mainly on the face and upper torso, develops in 88% of patients, and is severe in 12%. Severe rash has led to *Staphylococcus aureus* sepsis and abscesses that require incision and drainage. Sunlight can exacerbate dermatologic reactions, and hence patients should limit sun exposure, use a sun block, and wear protective clothing.

Very rarely, cetuximab has been associated with *interstitial lung disease*, characterized by inflammation, scarring, and hardening of the lungs. One case of fatal interstitial pneumonitis with pulmonary edema has been reported. Whether cetuximab is truly the cause of these lung disorders has not been established.

The combination of cetuximab and irinotecan often causes *GI toxicity*, manifesting as diarrhea (72%), nausea (55%), abdominal pain (45%), vomiting (41%), anorexia (36%), and constipation (30%).

In clinical trials, hypomagnesemia developed in 55% of patients, and was severe in 6% to 17%. Magnesium supplements are often required.

Cetuximab can cross the placenta, but whether it causes fetal harm has not been studied. Until more is known, prudence dictates avoiding cetuximab during pregnancy.

103.5.1.1.4 Dosage, Administration, and Cost.

Cetuximab [Erbix] is given by slow IV infusion. Treatment consists of a loading dose (400 mg/m²) infused over 2 hours followed by weekly maintenance doses (250 mg/m²) infused over 1 hour. For an average adult, the monthly cost is about \$10,000.

103.5.1.2 Panitumumab

Panitumumab [Vectibix], approved in 2006, is a monoclonal antibody similar to cetuximab with respect to mechanism, indications, and adverse effects. The principal difference between the drugs is that panitumumab is a fully human antibody, whereas cetuximab is not. Like

cetuximab, panitumumab blocks EGFRs, causing inhibition of TK and, ultimately, apoptosis.

1206

At this time, the drug has only one indication: treatment of EGFR-expressing metastatic

1208

colorectal cancer in patients who have already received chemotherapy. The most common adverse effect is acne-like rash. Other adverse effects include fatigue, nausea, diarrhea, and hypomagnesemia. Because panitumumab is a fully human antibody, severe infusion reactions are less frequent than with cetuximab (1% vs. 3%). The usual dosage is 6 mg/kg IV every 2 weeks.

TABLE 102-4 Targeted Anticancer Drugs

Drug	Molecular Target	Structure	Indications	Major Toxicities
EGFR-Tyrosine Kinase Inhibitors				
Cetuximab [Erbix]	Inhibits EGFR	Antibody	EGFR-positive colorectal cancer and head and neck cancer	Rash, infusion reactions, interstitial lung disease
Panitumumab [Vectibix]	Inhibits EGFR	Antibody	EGFR-positive colorectal cancer	Rare infusion reactions, rash, rare interstitial pneumonitis
Gefitinib [Iressa]	Inhibits EGFR-TK	Small molecule	Non-small cell lung cancer	Rash, diarrhea, interstitial lung disease
Erlotinib [Tarceva]	Inhibits EGFR-TK	Small molecule	Non-small cell lung cancer	Blistering, GI perforation, interstitial lung disease
BRC-ABL Tyrosine Kinase Inhibitors				
Imatinib [Gleevec]	Inhibits BCR-ABL tyrosine kinase	Small molecule	Chronic myeloid leukemia, GI stromal tumors	Nausea, diarrhea, myalgia, edema, liver injury
Dasatinib [Sprycel]	Inhibits BCR-ABL tyrosine kinase	Small molecule	Chronic myeloid leukemia	Diarrhea, edema, liver injury, myelosuppression
Nilotinib [Tasigna]	Inhibits BCR-ABL tyrosine kinase	Small molecule	Chronic myeloid leukemia	Myelosuppression, QT prolongation
CD20-Directed Antibodies				
Rituximab [Rituxan]	Binds CD20 antigen, causing apoptosis and immune attack	Antibody	B-cell non-Hodgkin's lymphoma	Infusion reactions: fever, chills, nausea, urticaria

Ibritumomab tiuxetan/ yttrium-90 [Zevalin]	Binds CD20 antigen, causing radiation injury	Antibody/yttrium-90 hybrid	B-cell non- Hodgkin's lymphoma	Bone marrow suppression and infusion reactions
Tositumomab/ ¹³¹ I-tositumomab [Bexxar]	Binds CD20 antigen, causing immune attack and radiation injury	Antibody/iodine-131 hybrid	B-cell non- Hodgkin's lymphoma	Bone marrow suppression, infusion reactions, hypersensitivity reactions
Angiogenesis Inhibitors				
Bevacizumab [Avastin]	Binds VEGF and thereby inhibits angiogenesis	Antibody	Colorectal cancer and non-small cell lung cancer	Hypertension, GI perforation, impaired wound healing, thromboembolism, nephrotic syndrome
Proteasome Inhibitors				
Bortezomib [Velcade]	Inhibits proteasome activity	Small molecule	Multiple myeloma	Bone marrow suppression, GI disturbances, peripheral neuropathy, weakness
Other Targeted Anticancer Drugs				
Alemtuzumab [Campath]	Binds CD52 antigen	Antibody	B-cell chronic lymphocytic leukemia	Bone marrow suppression, infusion reactions and infection
Gemtuzumab ozogamicin [Mylotarg]	Binds CD33 antigen to deliver cytotoxic drug	Antibody/cytotoxic antibiotic hybrid	CD33-positive myeloid leukemia	Bone marrow suppression and infusion reactions
Lapatinib [Tykerb]	Binds HER2 and EGFR-TK	Small molecule	HER2-positive breast cancer	Cardiotoxicity

Sorafenib [Nexavar]	Cell surface and intracellular tyrosine kinases	Small molecule	Renal cell carcinoma	Rash, diarrhea, fatigue, hand-and-foot syndrome
Sunitinib [Sutent]	Multiple receptor tyrosine kinases	Small molecule	Renal cell carcinoma, GI stromal tumors	Fatigue, heart failure, hypertension
Temsirolimus [Torisel]	Inhibits mTOR	Small molecule	Renal cell carcinoma	Rash, fatigue, anemia, liver injury
Trastuzumab [Herceptin]	Binds HER2	Antibody	HER2-positive breast cancer	Cardiotoxicity and infusion reactions
Vorinostat [Zolinza]	Inhibits HDAC	Small molecule	Cutaneous T-cell lymphoma	Pulmonary embolism, fatigue, nausea, diarrhea, anemia, thrombocytopenia
EGFR-TK = epidermal growth factor receptor, which is coupled with tyrosine kinase (TK); HDAC = histone deacetylase, HER2 = human epider-mal growth factor receptor, mTOR = mammalian target of rapamycin, VEGF = vascular endothelial growth factor.				

103.5.1.3 Gefitinib

103.5.1.3.1 Therapeutic Use.

Gefitinib [Iressa] is approved for oral therapy of advanced *non–small cell lung cancer* (NSCLC) that has been refractory to first-line treatment (platinum- or docetaxel-based therapy). In clinical trials, between 8.2% and 19% of patients achieved an objective response. Unfortunately, postmarketing studies failed to show any survival benefit. As a result, gefitinib is now restricted to patients who have shown a response to the drug in the past, and to current users who are responding to it now. NSCLC is the most common form of lung cancer, and cells of this cancer often overexpress EGFRs.

103.5.1.3.2 Mechanism of Action.

Like cetuximab, gefitinib disrupts cellular processes regulated by EGFRs. However, unlike cetuximab, which acts on the cell surface to block EGFRs, gefitinib acts within the cell to inhibit an enzyme—tyrosine kinase—that is linked with EGFR. Under normal conditions, activation of EGFR leads to activation of tyrosine kinase, which in turn activates signaling

pathways that regulate cell proliferation and survival. By inhibiting EGFR-linked tyrosine kinase, gefitinib has the same effect as EGFR blockade: suppression of cell proliferation and promotion of apoptosis.

103.5.1.3.3 Responding Populations.

A mutation in the EGFR-tyrosine kinase gene predicts who will respond to gefitinib or erlotinib (see below). This mutation is more likely in women, Asians, and patients with the adenocarcinoma subtype of NSCLC. People in these populations are more likely to respond.

103.5.1.3.4 Pharmacokinetics.

Gefitinib is slowly absorbed from the GI tract. Plasma levels peak 3 to 7 hours after dosing. The drug undergoes extensive hepatic metabolism, primarily by CYP3A4, followed by excretion in the feces. The elimination half-life is 48 hours.

103.5.1.3.5 Adverse Effects.

Gefitinib is generally well tolerated. As with cetuximab, the most frequent reactions are diarrhea (48%) and acne-like rash (43%). Other fairly common reactions are dry skin (13%), nausea (13%), and vomiting (12%). Ocular effects—amblyopia, conjunctivitis, eye pain, and corneal erosion or ulceration—occur infrequently. Asymptomatic elevation of liver transaminases has been reported.

Interstitial lung disease (ILD) is the most serious adverse effect. This condition begins with acute-onset dyspnea, sometimes with cough or fever. Rapid deterioration may ensue. The overall incidence is about 1%, with one-third of cases being fatal. If respiratory symptoms develop, gefitinib should be interrupted and the patient evaluated. If ILD is diagnosed, gefitinib should not be used again. The risk of ILD is highest among patients with prior radiation or chemotherapy.

103.5.1.3.6 Drug and Herb Interactions.

Drugs that inhibit CYP3A4 (eg, itraconazole, ketoconazole) can decrease gefitinib metabolism, and may thereby increase its plasma level. Conversely, agents that induce CYP3A4 (eg, rifampin, phenytoin, carbamazepine, St John's wort) can accelerate gefitinib metabolism, and may thereby reduce its level. Likewise, drugs that lower gastric pH (eg,

histamine₂ antagonists, proton pump inhibitors, antacids) can decrease gefitinib absorption, and may thereby lower its level.

103.5.1.3.7 Use in Pregnancy and Lactation.

Gefitinib can harm the developing fetus, and hence should not be used by pregnant women. In laboratory animals, the drug decreased the number of live births, increased neonatal mortality, and reduced fetal weight. We don't know if gefitinib is safe during breast-feeding.

103.5.1.3.8 Preparations, Dosage, and Administration.

Gefitinib [Iressa] is available in 250-mg tablets. The usual dosage is 250 mg once a day, taken with or without food. Dosing should be interrupted if the patient develops severe rash, severe diarrhea, or ocular complications, and should be discontinued if ILD is diagnosed. For patients taking a potent inducer of CYP3A4, dosage may be increased to 500 mg/day.

103.5.1.4 Erlotinib

103.5.1.4.1 Actions and Use.

Erlotinib [Tarceva] has two indications: (1) advanced *non–small cell lung cancer*, but only when previous chemotherapy has failed; and (2) inoperable *pancreatic cancer*, but only in combination with gemcitabine. Like gefitinib, erlotinib inhibits tyrosine kinase coupled with EGFR, and thereby suppresses cell proliferation and promotes apoptosis. However, in contrast to gefitinib, erlotinib has been shown to prolong survival: In one trial of patients with NSCLC, median survival was 6.7 weeks with erlotinib, compared with 4.7 weeks with placebo. Survival was longest among patients who had never smoked and those with high levels of EGFR.

103.5.1.4.2 Pharmacokinetics.

Oral bioavailability is 60% in the absence of food, and nearly 100% in the presence of food. Plasma levels peak about 4 hours after dosing. In the blood, erlotinib is 93% bound to proteins. The drug undergoes extensive metabolism by hepatic CYP3A4, followed by excretion in the bile.

103.5.1.4.3 Adverse Effects.

Although erlotinib is generally well tolerated, adverse effects occur often. The most common are rash (75%), diarrhea (54%), nausea (33%), and vomiting (23%). Diarrhea can usually be managed with loperamide. Rarely, patients develop ILD, a potentially fatal condition that begins with dry cough and sudden onset of dyspnea (or sudden worsening of existing dyspnea). Hepatotoxicity, manifesting as asymptomatic elevation of liver transaminases, occurs in some patients. Rarely, erlotinib causes GI perforation or severe skin reactions, both of which can be fatal. In animal studies, erlotinib caused fetal death and abortion, and hence should not be used during pregnancy.

103.5.1.4.4 Drug Interactions.

Strong inhibitors of CYP3A4 (eg, itraconazole, clarithromycin, ritonavir) can decrease metabolism of erlotinib, causing its level to rise. Conversely, inducers of CYP3A4 (eg, rifampin, carbamazepine) can accelerate metabolism of erlotinib, causing its level to fall, sometimes dramatically. Erlotinib may increase the risk of bleeding in patients taking warfarin; close monitoring of prothrombin time or the INR (international normalized ratio) is recommended.

103.5.1.4.5 Preparations, Dosage, and Administration.

Erlotinib [Tarceva] is supplied in tablets (25, 100, and 150 mg). The recommended dosage is 150 mg once daily, taken at least 1 hour before eating or 2 hours after. Dosage reduction should be considered in patients who develop serious skin reactions or liver impairment, and in those taking inhibitors of CYP3A4. If symptoms of ILD develop, dosing should be interrupted until ILD has been ruled out.

103.5.1.5 Lapatinib

Lapatinib [Tykerb] is a small-molecule inhibitor of EGFR-tyrosine kinase and HER2 tyrosine kinase. Lapatinib and its use in breast cancer are discussed above.

103.5.2 BCR-ABL Tyrosine Kinase Inhibitors

The BCR-ABL tyrosine kinase inhibitors are the preferred agents for treating *chronic myeloid leukemia* (CML). Three of these drugs are available: imatininib, dasatinib, and nilotinib. Imatinib

was introduced in 2001, and quickly became the “gold standard” for CML therapy.

Unfortunately, relapse can occur, owing to evolution of subclones that have imatinib-resistant BCR-ABL mutations. The two newer drugs—dasatinib and nilotinib—are active against all but one of these resistant subclones, and hence can be effective when patients no longer respond to imatinib.

103.5.2.1 Imatinib

103.5.2.1.1 Indications.

In 2001, imatinib [Gleevec] was approved for oral therapy of CML, but only after treatment with interferon alfa had failed. By 2003, because of clear superiority, imatinib had displaced interferon alfa as the initial treatment of choice. Imatinib may be continued as long as there is no evidence of progressive disease, and as long as side effects remain tolerable.

Imatinib is also approved for *myelodysplastic/myeloproliferative diseases, aggressive systemic mastocytosis, acute lymphoblastic leukemia, dermatofibrosarcoma protuberans, hypereosinophilic syndrome*, and unresectable and/or metastatic malignant *gastrointestinal stromal tumors* (GIST), a rare form of stomach/intestinal cancer. These are minor applications and are not discussed further.

103.5.2.1.2 CML and Its Treatment.

CML is a cancer in which myeloid cells undergo massive clonal expansion. The disease begins with a chronic phase, progresses through an accelerated phase, and ends with the blast crisis phase. The underlying cause is a genetic abnormality known as the *Philadelphia chromosome*, which is produced by translocation of genetic material between chromosomes 9 and 22. Because of this genetic change, CML cells make an abnormal, continuously active enzyme, called *BCR-ABL tyrosine kinase*. This enzyme phosphorylates, and thereby activates, as-yet unidentified regulatory proteins, which in turn inhibit apoptosis and stimulate excessive cell proliferation. Major treatment options are imatinib, interferon-based regimens, and stem cell transplantation, which is the only potentially curative treatment.

1208

1209

103.5.2.1.3 Mechanism of Action and Clinical Effects.

Imatinib is a highly specific competitive inhibitor of *BCR-ABL tyrosine kinase*. By inhibiting this enzyme, imatinib prevents the phosphorylation and resultant activation of regulatory proteins, and thereby suppresses proliferation of CML cells, and promotes apoptosis.

Imatinib is selective for cells that express BCR-ABL tyrosine kinase; normal cells are not affected. When tested during the chronic phase of CML, imatinib was superior to the combination of interferon alfa plus cytarabine. After 18 months, disease progression was stopped in 92% of imatinib users, compared with 74% of those getting interferon. Furthermore, imatinib was better tolerated. Long-term follow-up is needed to determine how long responses to imatinib will last, and whether imatinib prolongs survival.

Over time, resistance to imatinib may develop. Why? Because the genes that code for BCR-ABL can mutate, thereby causing production of imatinib-resistant forms of the enzyme.

103.5.2.1.4 Pharmacokinetics.

Imatinib is well absorbed following oral administration. Bioavailability is 98%. In the blood, the drug is highly bound to proteins. Imatinib undergoes extensive metabolism, primarily by hepatic CYP3A4, followed by excretion in the feces. The elimination half-lives of imatinib and its major active metabolite are 18 hours and 40 hours, respectively.

103.5.2.1.5 Adverse Effects.

Imatinib causes adverse effects in most patients. The incidence and severity of adverse effects is lowest during the chronic phase of CML, higher during the accelerated phase, and highest during blast crisis. However, even though adverse effects occurred often during trials, discontinuation because of them was uncommon: only 1% during the chronic phase, 2% during the accelerated phase, and 5% during blast crisis. Common reactions include nausea (55% to 68%), vomiting (28% to 54%), diarrhea (33% to 49%), rash (32% to 39%), headache (24% to 28%), fatigue (24% to 33%), fever (14% to 38%), and musculoskeletal complaints: muscle cramps (25% to 46%), muscle pain (27% to 37%), and arthralgia (21% to 24%). Fluid retention occurs in 52% to 68% of patients, and may lead to pleural effusion, pericardial effusion, pulmonary edema, or ascites. Neutropenia and thrombocytopenia develop often. Accordingly, complete blood counts should be obtained weekly during the first month of treatment, biweekly during the second month, and periodically thereafter. Hepatotoxicity, as evidenced by severe elevations of transaminases or bilirubin, develops in 1.1% to 3.5% of patients. Imatinib is teratogenic in rats and should be avoided, if possible, during pregnancy. Information on long-term toxicity is lacking.

103.5.2.1.6 Drug Interactions.

Imatinib is a substrate for and competitive inhibitor of CYP3A4, CYP2C9, and CYP2D6. By inhibiting these isozymes, imatinib can raise levels of warfarin and other drugs that are metabolized by them. Drugs that inhibit CYP3A4 (eg, ketoconazole, erythromycin) can raise levels of imatinib. Conversely, drugs that induce CYP3A4 (eg, carbamazepine, rifampin, St. John's wort) can reduce levels of imatinib.

103.5.2.1.7 Preparations, Dosage, and Administration.

Imatinib [Gleevec] is supplied in 100- and 400-mg tablets. The dosage for adults with CML is 400 mg/day (during the chronic phase) and 600 mg/day during the accelerated phase or during blast crisis. The dosage for children with CML is 260 mg/m²/day (during the chronic phase). The dosage for adults with GIST is 400 or 600 mg/day.

103.5.2.2 Dasatinib

Dasatinib [Sprycel], approved in 2006, is indicated for all three phases of CML: chronic, accelerated, and blast crisis. At this time, the drug is reserved for patients who are unresponsive to or intolerant of imatinib.

Dasatinib inhibits BCR-ABL kinase more effectively than imatinib. Why? First, dasatinib binds to both the active and inactive conformations of BCR-ABL tyrosine kinase, whereas imatinib only binds to the inactive conformation. Second, dasatinib binds the enzyme with greater affinity than imatinib. Third, dasatinib binds a wider variety of protein kinases. As a result of these differences, dasatinib is active against nearly all imatinib-resistant mutations. In fact, the only exception is the T315I mutation, which is resistant to all available drugs.

Adverse effects of dasatinib are much like those of imatinib, with one important exception: Dasatinib produces more myelosuppression. Because of this difference, dasatinib seems unlikely to replace imatinib as first-line therapy. Dasatinib has the potential to prolong the QT interval, but the clinical significance is unclear.

Levels of dasatinib can be affected by other drugs. Dasatinib is a substrate for CYP3A4, and hence drugs that induce CYP3A4 can lower dasatinib levels, and drugs that inhibit CYP3A4 can raise dasatinib levels. Solubility of dasatinib is pH dependent, and hence drugs that raise

gastric pH (antacids, proton pump inhibitors, H₂-receptor blockers) can reduce dasatinib absorption.

103.5.2.3 Nilotinib

Nilotinib [Tasigna], approved in 2007, is indicated for chronic-phase and accelerated-phase CML—but only in patients resistant to or intolerant of dasatinib. Like imatinib, the drug binds to the inactive form of BCR-ABL. However, the binding affinity is much greater. Like dasatinib, nilotinib is active against all imatinib-resistant clones, except those with the T315I mutation.

In general, patients tolerate nilotinib better than imatinib. The most common adverse effects are thrombocytopenia, neutropenia, rash, pruritus, nausea, fatigue, headache, and constipation. Nilotinib can prolong the QT interval, and thereby poses a risk of severe dysrhythmias and sudden cardiac death.

Like dasatinib, nilotinib is a substrate for CYP3A4, and hence drugs that induce CYP3A4 can lower nilotinib levels, and drugs that inhibit CYP3A4 can raise nilotinib levels.

Nilotinib is available in 200-mg capsules, and dosed at 400 mg twice daily.

103.5.3 CD20-Directed Antibodies

Antibodies directed against CD20 are used to treat B-cell non-Hodgkin's lymphoma. What's CD20? It's a molecule found on the cell membrane surface of B lymphocytes (B cells), which are important components of the immune system (see [Chapter 66](#)). Most other cells lack CD20. When antibodies bind with CD20, they trigger an immune attack against the B cell itself. Since most other cells do not have CD20, injury is limited to normal and malignant B lymphocytes.

At this time, three products containing anti-CD20 antibodies are available. Two of these products—ibritumomab [Zevalin] and tositumomab [Bexxar]—consist of a monoclonal antibody that has been linked with a radioactive isotope. With these drugs, cell kill results largely from radiation damage, rather than from immune attack. The third agent—rituximab [Rituxan]—has no radioactivity, and hence cell kill results from immune attack by the antibody (and also by apoptosis).

103.5.3.1 Rituximab

103.5.3.1.1 Actions and Use.

Rituximab [Rituxan] is a monoclonal antibody indicated for IV therapy of *B-cell non-Hodgkin's lymphoma*. Rituximab is directed against the CD20 antigen, which is present on the surface of most normal and malignant B cells. Binding of rituximab recruits components of the immune system, which then cause cell lysis. In one study, rituximab produced a complete response in 6% of patients, and another 42% experienced a partial response (50% or greater reduction in tumor burden). The recommended dosage is 375 mg/m² given by slow infusion once a week for 4 weeks. A 4-week course costs about \$11,000.

1209

1210

As discussed in [Chapter 72](#), rituximab is also used for rheumatoid arthritis.

103.5.3.1.2 Adverse Effects.

103.5.3.1.2.1 Infusion Reactions.

Rituximab can cause severe infusion-related hypersensitivity reactions. Prominent symptoms are hypotension, bronchospasm, and angioedema. More than 70 cases of severe hypersensitivity have been reported, including several fatalities. Management includes slowing or discontinuing the infusion and injecting epinephrine.

103.5.3.1.2.2 Tumor Lysis Syndrome (TLS).

Rapid and massive death of tumor cells can lead to TLS, characterized by acute renal failure, hyperkalemia, hypocalcemia, hyperuricemia, or hyperphosphatemia. Rarely, the syndrome proves fatal. TLS begins within 12 to 24 hours of the first rituximab infusion. The risk of TLS is increased by a high tumor burden. Management includes dialysis and correction of fluid and electrolyte abnormalities.

103.5.3.1.2.3 Mucocutaneous Reactions.

Rituximab has been associated with severe mucocutaneous reactions, including Stevens-Johnson syndrome, lichenoid dermatitis, vesiculobullous dermatitis, and toxic epidermal necrolysis. Deaths have occurred. Reaction onset is typically 1 to 3 weeks after rituximab exposure. Patients who experience these reactions should seek immediate medical attention, and should not receive rituximab again.

103.5.3.1.2.4 Hepatitis B Reactivation.

There have been reports of hepatitis B virus (HBV) reactivation, leading to fulminant hepatitis, hepatic failure, and death. Patients at high risk of HBV should be screened before getting rituximab. Asymptomatic carriers should be closely monitored for clinical and laboratory signs of active HBV infection while taking rituximab, and for several months after stopping.

103.5.3.1.2.5 Progressive Multifocal Leukoencephalopathy (PML).

Rituximab has been associated with rare cases of PML, a severe infection of the CNS caused by reactivation of the JC virus, an opportunistic pathogen resistant to all available drugs.

103.5.3.1.2.6 Other Adverse Effects.

Like other monoclonal antibodies, rituximab can cause a flu-like syndrome, especially during the initial infusion. Symptoms include fever, chills, nausea, vomiting, and myalgia. Rituximab causes transient neutropenia, but this does not appear to increase the risk of infection.

103.5.3.2 Ibritumomab Tiuxetan Linked with Yttrium-90

103.5.3.2.1 Description, Actions, and Use.

Ibritumomab tiuxetan (IT), marketed as *Zevalin*, is a compound molecule composed of ibritumomab (a monoclonal antibody) that has been covalently bound with tiuxetan. Like rituximab, IT binds selectively with the CD20 antigen present on most normal and malignant B cells. However, unlike rituximab, which is used by itself to treat cancer, IT is first linked with yttrium-90 (Y90), a beta particle–emitting radioisotope. When the IT-Y90 complex binds with cellular CD20 antigens, cell kill results from radiation-induced injury, rather than from injury caused by ibritumomab itself. Because beta particles have a relatively short path length (about 5 mm), injury is restricted to CD20-containing cells and to neighboring cells within a 5-mm radius. The radioactive drug poses no danger to persons in proximity. IT-Y90 was the first anticancer treatment to employ an antibody complexed with a radioactive compound. Like rituximab, IT-Y90 is approved for *low-grade, B-cell non-Hodgkin's lymphoma*. Therapy with IT-Y90 is expensive: A single course costs about \$30,000.

Before patients receive IT-Y90, they are given two small doses of rituximab, 7 to 9 days apart. The contribution of rituximab is twofold. First, it binds with circulating B cells, and thereby greatly reduces their numbers. Second, it occupies nonspecific binding sites that could otherwise attract IT-Y90, and hence would reduce the amount of IT-Y90 available to bind with target cells. For the purpose of diagnostic imaging, the first dose of rituximab is accompanied by a small dose of IT that has been linked to radioactive indium-111.

103.5.3.2.2 Adverse Effects.

Adverse effects of treatment are due to IT-Y90 itself and to the rituximab given before it. As noted above, rituximab can cause severe infusion reactions. With IT-Y90, hematologic toxicity is the major concern: severe, prolonged cytopenias develop in more than 50% of patients. Counts of neutrophils and platelets reach their nadir 7 to 9 weeks after treatment, and take 3 to 7 weeks to recover. In clinical trials, about 30% of patients developed infection or febrile neutropenia; of these, 7% required hospitalization. Deaths have occurred. Because of its hematologic toxicity, IT-Y90 is contraindicated for patients with (1) lymphoma bone marrow involvement of 25% or more or (2) limited bone marrow reserve (eg, platelet count below 100,000/mm³ or neutrophil count below 1500/mm³; history of prior myeloablative therapy).

103.5.3.3 Bexxar (Tositumomab with ¹³¹I-Tositumomab)

103.5.3.3.1 Description, Actions, and Use.

Bexxar is the trade name for a regimen that consists of (1) *tositumomab*, a monoclonal antibody, and (2) ¹³¹I-*tositumomab*, tositumomab covalently linked with radioactive iodine-131. This regimen, which is the second to employ a radiolabeled antibody, is very similar in mechanism and uses to the Zevalin regimen (ibritumomab tiuxetan/yttrium-90), which was the first to employ a radiolabeled antibody. Like the Zevalin regimen, the Bexxar regimen is both very toxic and very expensive: The cost of a single course (for the drug alone) is over \$30,000.

How does Bexxar kill cancer cells? Through a combination of immune activation and radiation damage. Like ibritumomab and rituximab, tositumomab binds selectively with the CD20 antigen found on the surface of most normal and malignant B cells. This binding stimulates an immune attack on the cell, with three possible results: complement-dependent

cytotoxicity, antibody-dependent cytotoxicity, and induction of apoptosis (programmed cell death). Cell death also results when ^{131}I -tositumomab binds with the CD20 antigen, thereby exposing target cells to a high dose of ionizing radiation.

Treatment is performed in two steps, called the *dosimetric step* and the *therapeutic step*. The dosimetric step is conducted to determine, for each patient, the specific dose of radiation to be given in the therapeutic step.

Bexxar is approved for CD20-positive follicular *B-cell non-Hodgkin's lymphoma* (NHL), a form of low-grade B-cell NHL. However, the drug should be used only if the cancer (1) is refractory to rituximab and (2) has relapsed following chemotherapy. In clinical trials, Bexxar produced an objective response in 63% of patients, and complete remission in 29%. The median duration of the response was 16 to 25 months.

103.5.3.3.2 Adverse Effects.

Like Zevalin, Bexxar can cause *severe, prolonged cytopenias*. Neutropenia (63%) and thrombocytopenia (53%) are most common, often leading to infections (45%) and hemorrhage (12%). Management may require infusion of blood products (platelets and red blood cells) as well as treatment with a hematologic growth factor (epoetin alfa, granulocyte colony-stimulating factor). To monitor hematologic status, complete blood counts should be obtained at baseline and then weekly for 10 to 12 weeks. Like Zevalin, Bexxar is contraindicated for patients with lymphoma bone marrow involvement of 25% or more and for those with limited bone marrow reserve.

Hypersensitivity reactions, including anaphylaxis, occur in 6% of patients. Medication for treating severe reactions (epinephrine, antihistamines, glucocorticoids) should be immediately available.

Many patients experience *infusional toxicity*, either during the infusion or within 48 hours after. Symptoms include fever, rigors, chills, sweating, hypotension, dyspnea, nausea, and bronchospasm. Pretreatment with acetaminophen or diphenhydramine may help.

The radioactive iodine in ^{131}I -tositumomab can damage the thyroid gland, causing *hypothyroidism*. To protect the thyroid, patients should take oral potassium iodide (tablets or solution), starting at least 24 hours before the dosimetric dose and continuing for 2 weeks after the therapeutic dose.

Gastrointestinal toxicity is seen in 38% of patients. Symptoms include nausea, vomiting, abdominal pain, and diarrhea.

Secondary malignancies—myelodysplastic syndrome and/or acute leukemia—occur in 2% to 3% of patients, usually within 3 years of treatment.

103.5.3.3.3 Use in Pregnancy and Lactation.

Radioactive iodine can harm the developing thyroid gland. Irreversible hypothyroidism may result. Accordingly, Bexxar is classified in *Food and Drug Administration (FDA) Pregnancy*

1210

1211

Category X, and hence must not be used during pregnancy. Radioiodine and (probably) tositumomab are excreted in breast milk, posing a risk to the breast-fed infant. Mothers should be warned not to breast-feed while receiving Bexxar.

103.5.3.3.4 Elimination of Iodine-131.

Elimination of iodine-131 occurs by radioactive decay and excretion in the urine. About 67% is cleared by 5 days after the infusion. Of the amount not eliminated through radioactive decay, 98% is eliminated in the urine.

103.5.3.3.5 Radiation Precautions.

For several days after treatment, persons in close proximity to the patient receiving Bexxar could be harmed by radiation from iodine-131. Therefore, prior to discharge, the patient should be given oral and written instruction on how to minimize exposure of family, friends, and the general public. Specific measures include staying at least 9 feet from others, sleeping alone, maintaining sole bathroom use (owing to urinary radiation excretion), avoiding contact with children and pregnant women, refraining from travel by plane or mass transit, and avoiding prolonged car travel with other people.

103.5.4 Angiogenesis Inhibitors

Angiogenesis inhibitors suppress formation of new blood vessels, and thereby deprive solid tumors of the expanding blood supply they need for continued growth. It is important to note, however, that although tumor growth is suppressed, angiogenesis inhibitors, by themselves, cannot kill tumor cells that already exist. At this time, only one angiogenesis inhibitor—bevacizumab—is approved for treating cancer. The history and unique potential of the angiogenesis inhibitors are discussed in [Box 102-1](#).

103.5.4.1 Bevacizumab

In 2004, bevacizumab [Avastin] became the first angiogenesis inhibitor approved for clinical use. In patients with metastatic colorectal cancer, the drug can delay tumor progression and prolong life. Unfortunately, it can also cause life-threatening adverse effects, including GI perforation, hemorrhage, and thromboembolism.

103.5.4.1.1 Mechanism of Action.

Bevacizumab is a monoclonal antibody that binds with vascular endothelial growth factor (VEGF), an endogenous compound that stimulates blood vessel growth. Binding with bevacizumab prevents VEGF from binding with its receptors on vascular endothelial cells, and thereby prevents VEGF from promoting new vessel formation. As a result, further tumor growth is inhibited.

103.5.4.1.2 Therapeutic Use.

Bevacizumab has three approved uses: (1) metastatic *cancer of the colon or rectum*, in combination with a regimen based on IV 5-fluorouracil (5-FU); (2) metastatic *HER 2-negative breast cancer*; and (3) *nonsquamous non-small cell lung cancer* (NSCLC), in combination with carboplatin and paclitaxel. In one trial studying colorectal cancer, patients received either (1) IFL (irinotecan, 5-FU, leucovorin) or (2) IFL plus bevacizumab. The result? Adding bevacizumab to IFL increased overall survival by 5 months, delayed tumor progression by 4 months, and increased the overall tumor response rate (45% vs. 35%). Investigational uses of bevacizumab include renal cell carcinoma and pancreatic cancer.

In addition to its use in cancer, bevacizumab is used off-label to treat the neovascular form of age-related macular degeneration (see [Chapter 103](#)).

103.5.4.1.3 Pharmacokinetics.

The pharmacokinetics of bevacizumab are poorly understood. We do know that the drug has an average half-life of 20 days, and that clearance occurs faster in males and in patients with a high tumor burden. However, there is no evidence that faster clearance reduces the clinical response. How clearance occurs is unknown.

103.5.4.1.4 Adverse Effects.

The most serious adverse effects are GI perforation, disruption of wound healing, pulmonary hemorrhage, thromboembolism, nephrotic syndrome, and hypertensive crisis. Less serious effects include diarrhea, epistaxis (nosebleeds), dizziness, headache, asthenia, and reduced appetite.

During clinical trials, 2% of patients developed *GI perforation*, with or without abscess formation. Some cases were fatal. Primary symptoms are abdominal pain in association with constipation and vomiting. If GI perforation occurs, bevacizumab should be stopped and never used again.

Bevacizumab *impairs wound healing* and can induce wound dehiscence (splitting open). Because of these effects, if bevacizumab is initiated too soon after surgery, or if it is not discontinued soon enough before surgery, impaired wound healing can result. To minimize healing complications, current guidelines suggest waiting at least 28 days after surgery before using the drug, and stopping the drug at least 28 days before elective surgery.

When used to treat NSCLC, bevacizumab has caused life-threatening *pulmonary hemorrhage*. The risk of a lifethreatening or fatal bleed is very high (31%) in patients with squamous cell histology, and much lower (4%) in those with non-squamous cell histology. Onset of bleeding is sudden and presents as major or massive hemoptysis (expectoration of blood).

When added to a regimen based on 5-FU, bevacizumab doubles the risk of *arterial thromboembolic events*, including ischemic stroke, myocardial infarction, and transient ischemic attacks. Death has occurred. Patients who experience a thromboembolic event should stop bevacizumab and never use it again.

In clinical trials, *nephrotic syndrome* (severe kidney damage) developed in 0.5% of patients. One patient required dialysis, and one died. Patients should be monitored for development or worsening of proteinuria, a sign of kidney injury. If moderate to severe proteinuria occurs, bevacizumab should be withdrawn.

Bevacizumab can cause *severe hypertension* that may persist for months after the drug is withdrawn. A few patients developed hypertensive encephalopathy, and one experienced

subarachnoid hemorrhage. Blood pressure should be monitored in all patients using the drug. If severe hypertension develops, bevacizumab should be permanently discontinued.

103.5.4.1.5 Effect in Pregnancy.

Angiogenesis is critical to fetal development, and hence angiogenesis inhibition is likely to cause fetal harm. Although human data are lacking, animal studies indicate that bevacizumab decreases fetal weight, increases fetal resorption, and can promote gross malformations. Currently, bevacizumab is classified in *FDA Pregnancy Risk Category C*, and should be used only if the benefits to the mother are judged to outweigh the risks to the fetus.

103.5.4.1.6 Dosage, Administration, and Cost.

The recommended dosage is 5 mg/kg IV every 2 weeks. Infusion time is 90 minutes for the first dose, then 60 minutes for the second dose (if the first dose was well tolerated), and 30 minutes thereafter (if the second dose was well tolerated). Treatment should be interrupted 28 days before elective surgery, and not resumed for at least 28 days after major surgery. Treatment should be permanently discontinued in the event of GI perforation, serious bleeding, thromboembolism, nephrotic syndrome, or hypertensive crisis. Bevacizumab is expensive, costing over \$5500/month (\$66,000/year).

103.5.4.2 Thalidomide

Thalidomide [Thalomid] is a drug with complex pharmacologic actions, including the ability to cause severe birth defects. In the United States, thalidomide has two approved indications (1) erythema nodosum leprosum, a complication of leprosy and (2) multiple myeloma, a cancer of the bone marrow. Promising results have also been seen with other cancers, including plasma cell leukemia and various solid tumors, including renal cell carcinoma, AIDS-related Kaposi's sarcoma, and cancers of the brain, breast, ovary, prostate, and colon. Anticancer effects are thought to derive from (1) effects on the immune system and (2) inhibition of angiogenesis (growth of blood vessels; see [Box 102-1](#)). Compared with traditional anticancer drugs, thalidomide is relatively well tolerated, but can cause clinically important neuropathy, sedation, and constipation. Neuropathy can be a chronic dose-limiting toxicity. Because thalidomide is a powerful teratogen, patients must comply with a strict set of FDA-mandated safeguards, known as the System for Thalidomide Education and Prescribing Safety, or S.T.E.P.S. The history and pharmacology of thalidomide, as well as the S.T.E.P.S. program, are discussed at length in [Chapter 106 \(Box 106-1\)](#).

1211

1213

103.5.4.2.1

BOX 102-1 Special Interest Topic

103.5.4.2.1.1

ANGIOGENESIS INHIBITORS: NO FLOW—NO GROW

Like all other tissues, tumors need blood vessels to provide nutrients and oxygen. To ensure adequate blood flow, tumor cells induce angiogenesis—growth of new blood vessels. Without new vessels, tumors could not grow. In fact, their maximum size would be limited to 2 mm³ (about the size of a pinhead). Because tumors require their own blood supply, drugs that block angiogenesis have the potential to profoundly limit tumor expansion. Furthermore, because angiogenesis inhibitors attack the blood supply, rather than the tumor itself, they should be active against a broad range of cancer types.

The field of angiogenesis inhibition owes much to Dr. Judah Folkman and his colleagues at Harvard Medical School. In 1971, Dr. Folkman discovered tumor-induced angiogenesis, and postulated that inhibitors of the process could cause tumor starvation. For many years, Folkman's lab was unable to find an angiogenesis inhibitor safe enough to use. Then, in 1997, the group reported dramatic results with two new compounds: angiostatin and endostatin. These agents were compared with cytotoxic drugs in mice with three kinds of primary tumors. Initially, both treatments caused tumor regression. However, with repeated rounds of therapy, the tumors developed resistance to the cytotoxic agents. In contrast, after six rounds of antiangiogenesis treatment, the tumors regressed to microscopic size—and then remained dormant a long time. Furthermore, the angiogenesis inhibitors were devoid of adverse effects, in sharp contrast to the cytotoxic drugs.

103.5.4.2....

Angiogenesis in Normal Tissues and in Tumors

In normal tissues, angiogenesis occurs during fetal development, growth, wound repair, and the uterine cycle. New blood vessels are derived from endothelial cells—the flat cells that form the inner lining of blood vessels. Angiogenesis has four basic steps:

- Activation of endothelial cells in an existing blood vessel
- Production, by the endothelial cells, of matrix metalloproteinases (MMPs), which break down the extracellular matrix of the surrounding tissue

- Proliferation and migration of endothelial cells
- Assembly of the endothelial cells into new blood vessels

This process is tightly regulated by two groups of opposing factors: activators of endothelial cell growth and inhibitors of endothelial cell growth. At least 35 endogenous factors are known to activate endothelial cell growth and migration. Important among these are

- Vascular endothelial growth factor (VEGF)
- Basic fibroblast growth factor (bFGF)
- Epidermal growth factor
- Platelet-derived growth factor
- Placental growth factor
- Interleukin-8
- Tumor necrosis factor-alpha (TNF-alpha)
- Angiogenin
- Angiotropin

Naturally occurring inhibitors of endothelial growth include angiostatin, endostatin, interferons, platelet factor 4, thrombospondin, and three tissue inhibitors of metalloproteinase (TIMP-1, TIMP-2, and TIMP-3).

Tumors can stimulate angiogenesis by releasing growth factors. Two such factors—VEGF and bFGF—are produced by many tumors, and appear important for promoting and sustaining tumor growth. In tumors, a good blood supply is associated with aggressive growth and increased ability to metastasize. Interestingly, MMPs, which break down the matrix that holds cells together, are required for both angiogenesis and metastatic spread.

Comparison with Cytotoxic Anticancer Drugs

The angiogenesis inhibitors differ from cytotoxic drugs in four important ways. First, angiogenesis inhibitors are safer. Second, angiogenesis inhibitors can be used without interruption. Third, tumor resistance to angiogenesis inhibitors does not develop. Fourth, angiogenesis inhibitors can prolong life without causing tumor regression.

Angiogenesis inhibitors are generally *safer* than cytotoxic anticancer drugs. Unlike cytotoxic drugs, which attack *all* proliferating cells, angiogenesis inhibitors have limited effects. Accordingly, these agents do not cause myelosuppression, GI ulceration, or hair loss—toxicities that are common with the cytotoxic drugs. However, because of their effects on blood vessels, angiogenesis inhibitors are likely to interfere with wound healing and fetal development, and they may be harmful to growing children. In addition, they increase the risk of thromboembolism and hypertension. As we gain more experience with these drugs, additional toxicities may be revealed.

Angiogenesis inhibitors can be *used continuously*. Why? Because these drugs do not cause dose-related myelosuppression and mucositis. Cytotoxic drugs must be used intermittently, so as to permit recovery of bone marrow and mucosal tissue.

In long-term preclinical studies, *no tumor resistance* to angiogenesis inhibitors has been observed. By contrast, resistance is common with cytotoxic drugs. Why the difference? Cytotoxic drugs are directed against cancer cells, which are heterogeneous and genetically unstable. As a result, drug-resistant variants can readily evolve and emerge. In contrast, angiogenesis inhibitors are directed at endothelial cells, which are genetically stable, and hence are unlikely to evolve into potentially resistant forms.

With angiogenesis inhibitors, the treatment goal is *tumor stabilization*, rather than tumor regression. Although these drugs can block formation of new blood vessels, they do not cause existing vessels to dissolve. Hence, they can block tumor growth, but may not cause an existing tumor to shrink. When cytotoxic drugs are tested, the clinical endpoint is tumor regression. In contrast, when angiogenesis inhibitors are tested, the endpoint is prolongation of life; the tumor may or may not get smaller.

103.5.4.2....

A New Treatment Paradigm

Angiogenesis inhibitors may enable a completely new approach to cancer therapy: long-term maintenance, instead of outright cure. By suppressing growth of new blood vessels, angiogenesis inhibitors can stabilize existing tumors and prevent growth of new ones. With continuous therapy, we may be able to keep the cancer in check indefinitely, even though it is unlikely to go away. Hence, although treatment may not eliminate the cancer, chronic therapy may still permit a long life. In essence, cancer would become a chronic but treatable disease, much like hypertension or diabetes—diseases that we can manage with drugs, even though we can't cure them. Perhaps the angiogenesis inhibitors will permit cancer patients to live long and otherwise healthy lives, just as drugs have done for patients with these other once-fatal diseases.

103.5.4.2....

Clinical Status

More than 60 angiogenesis inhibitors are in clinical trials, and one agent—bevacizumab [Avastin]—has been approved for general use (see chapter body). These drugs work by four basic mechanisms: (1) inhibition of MMPs, (2) direct inhibition of endothelial cell proliferation and migration, (3) antagonism of angiogenic growth factors, and (4) inhibition of integrin, a protein found on the endothelial cell surface. In addition, they may improve delivery of chemotherapy to tumors. Specific agents under investigation include *marimastat* (which inhibits MMP), *endostatin* (which directly inhibits endothelial cells), and *vitaxin* (which blocks integrin). Target diseases include melanoma, Kaposi's sarcoma, malignant glioma, and cancers of the breast, lung, ovary, prostate, colon, and pancreas.

103.5.5 Proteasome Inhibitors

What are proteasomes, and how does inhibiting them harm cells? Proteasomes are intracellular multienzyme complexes that degrade proteins. Their physiologic role is to rid cells of proteins that are not needed, including proteins that regulate transcription, cell adhesion, apoptosis, and progression through the cell cycle. Proteasome inhibitors can cause these proteins to accumulate, and can thereby disrupt various aspects of cell physiology. In cancer cells, these drugs appear to promote accumulation of proteins that promote apoptosis (programmed cell death). Why this effect is limited largely to cancer cells is not clear, but may be related to inhibition of NF-kappa

B, a transcription factor critical to the growth of several types of cancer, including multiple myeloma.

103.5.5.1 Bortezomib

103.5.5.1.1 Actions.

Bortezomib [Velcade], approved in 2004, is the first proteasome inhibitor available for general use. The drug inhibits a specific proteasome, known as the 26S proteasome, and thereby alters the concentration of proteins that regulate cell growth and division. The result is reduced cell viability, increased apoptosis, and increased sensitivity to the lethal effects of radiation and traditional anticancer drugs. Does bortezomib hurt normal cells too? Yes. However, *in vitro* studies suggest that normal cells are less vulnerable than cancer cells.

103.5.5.1.2 Therapeutic Use.

Bortezomib is approved for (1) *multiple myeloma*, both as first-line therapy and for patients who have not responded adequately to other therapies (eg, thalidomide, autologous stem cell transplantation); and (2) *mantle cell lymphoma* in patients with at least 1 prior year of therapy. In a clinical trial involving multiple myeloma patients who had received an average of six prior therapies, treatment with bortezomib, by itself, produced a measurable response in 35% of patients, and complete cancer regression in 4%. The median response duration was 1 year. Given that these patients were, in essence, refractory to virtually all other treatments, these results are especially impressive. Bortezomib is now being studied in a variety of solid tumors, including non-Hodgkin's lymphoma, colorectal cancer, and lung cancer.

103.5.5.1.3 Adverse Effects.

Adverse effects are common and often serious. The most frequent reactions are weakness (65%), nausea (64%), and diarrhea (51%). Also common are hematologic effects—thrombocytopenia (43%), anemia (32%), and neutropenia (24%)—as well as constipation (43%), anorexia (43%), peripheral neuropathy (37%), fever (36%), and postural hypotension (12%). Bortezomib is fetotoxic in rabbits, and has been classified in FDA Pregnancy Risk Category D. Accordingly, pregnancy should be avoided.

103.5.5.1.4 Drug Interactions.

No formal studies on drug interactions have been conducted. However, we do know that bortezomib is metabolized in the liver by cytochrome P450 isozymes. Accordingly, inhibitors or inducers of these isozymes might be expected to alter bortezomib levels.

103.5.5.1.5 Dosage, Administration, and Cost.

Bortezomib [Velcade] is administered by IV bolus in repeated 3-week cycles. One cycle consists of a single dose (1.3 mg/m^2) on days 1, 4, 8, and 11, followed by a 10-day rest period. In the event of painful peripheral neuropathy or any other severe toxicity, interruption of treatment and/or dosage reduction may be needed. Bortezomib is expensive: The cost of an average course (5.5 cycles) is about \$24,000.

103.5.6 Other Targeted Drugs

103.5.6.1 Sorafenib

Sorafenib [Nexavar], approved in 2005, is an oral tyrosine kinase inhibitor indicated for *advanced renal cell carcinoma*. The drug inhibits multiple cell-surface and intracellular kinases that are associated with angiogenesis, apoptosis, and cell proliferation. The most common adverse effects are diarrhea (43%), rash (40%), fatigue (37%), and hand-and-foot syndrome (30%). Between 15% and 20% of patients develop hypertension. Nausea and vomiting are usually mild. The recommended dosage is 400 mg PO twice daily. Dosing should be done on an empty stomach to optimize absorption.

103.5.6.2 Sunitinib

Sunitinib [Sutent], approved in 2006, is an oral tyrosine kinase inhibitor with two indications: *advanced renal cell carcinoma* and *GI stromal tumor (GIST)* in patients unresponsive to or intolerant of imatinib. The drug inhibits multiple receptor tyrosine kinases, and thereby disrupts angiogenesis, cellular growth, and tumor metastasis.

The most common adverse effect is fatigue (42%). Of much greater concern, about 15% of patients develop irreversible heart failure, and hence cardiac function should be monitored closely. About 25% of patients develop mild to moderate hypertension, which responds to standard antihypertensive drugs. Leukopenia and anemia are relatively common, owing to

moderate myelosuppression. Other adverse effects include mucositis, abnormal liver function tests, and GI effects (nausea, vomiting, and diarrhea).

Sunitinib is a substrate for CYP3A4, and hence medications that inhibit CYP3A4 (eg, ketoconazole, erythromycin) can raise levels of sunitinib and increase toxicity. Conversely, drugs that induce CYP3A4 (eg, carbamazepine, rifampin, St. John's wort) can reduce levels and thereby decrease efficacy.

The recommended dosage is 50 mg PO once daily, taken with or without food. The dosing cycle consists of 4 weeks of treatment followed by 2 weeks off.

103.5.6.3 Gemtuzumab Ozogamicin

Gemtuzumab ozogamicin [Mylotarg], approved in 2000, is a novel drug indicated for patients with CD33-positive *acute myeloid leukemia* (AML). Candidates should be in their first relapse after conventional chemotherapy (eg, cytarabine plus idarubicin), at least 60 years old, and unable to tolerate further conventional treatment. In clinical trials, gemtuzumab produced complete remission in 15% to 30% of patients. Treatment consists of two 2-hour infusions (9 mg/m² each) given 2 weeks apart.

1213

1214

Gemtuzumab has a unique structure and mechanism. The drug consists of a *monoclonal antibody* (directed against CD33 antigens) coupled with a *cytotoxic antibiotic* (a derivative of calicheamicin). CD33 antigens are found on the surface of leukemic blasts in more than 90% of patients with AML, and also on the surface of normal and leukemic myeloid colony-forming cells—but *not* on pluripotent hematopoietic stem cells. The drug works as follows: (1) the antibody portion binds to a CD33 antigen on the cell surface, (2) the resultant complex becomes internalized, and (3) the antitumor antibiotic is released, undergoes conversion to its active form, binds with DNA, and causes strand breakage. The result is cell death.

Principal adverse effects are *acute infusion reactions* and *myelosuppression*. Infusion reactions generally develop shortly after the infusion and resolve in 2 to 4 hours. Manifestations include chills (62%), fever (61%), nausea (38%), vomiting (32%), and hypotension (11%).

Pretreatment with acetaminophen plus an antihistamine is recommended. Because of damage to myeloid colony-forming cells, severe neutropenia and thrombocytopenia occur in 90% of patients. However, because pluripotent hematopoietic stem cells are spared, myelosuppression is reversible. Some patients show signs of liver damage (eg, increased levels of bilirubin and aminotransferase). Veno-occlusive disease of the liver has been reported, usually following

transplantation of stem cells from donor bone marrow. Gemtuzumab is *teratogenic* and *fetotoxic* in laboratory animals, and hence is classified in *FDA Pregnancy Risk Category D*.

103.5.6.4 Temisirolimus

Temisirolimus [Torisel], approved in 2007, is indicated for IV therapy of *advanced renal cell carcinoma*. Following conversion to its active form—sirolimus—the drug inhibits mTOR (mammalian target of rapamycin), a protein kinase that helps regulate cell growth, proliferation, and survival. Inhibition of mTOR leads to G₁ arrest and apoptosis. Adverse effects, which are common, include weakness (51%), rash (47%), mucositis (41%), nausea (37%), edema (35%), anorexia (32%), dyspnea (28%), pain (28%), and fever (24%). Common laboratory abnormalities include anemia (94%), neutropenia (53%), hyperglycemia (38%), and increases in cholesterol (87%), triglycerides (83%), and alkaline phosphatase (68%). Sirolimus (the active metabolite of temisirolimus) is metabolized by CYP3A4, and hence levels of sirolimus can be altered by drugs that induce or inhibit CYP3A4. Temisirolimus is available in single-dose, 25-mg vials. The recommended dosage is 25 mg infused over 30 to 60 minutes once weekly, continuing until disease progression recurs or toxicity becomes intolerable.

103.5.6.5 Vorinostat

Vorinostat [Zolinza], approved in 2006, is the first representative of a new class of anticancer agents: the *histone deacetylase (HDAC) inhibitors*. The drug is approved for oral therapy of *cutaneous T-cell lymphoma* that has progressed or returned after treatment with two systemic therapies. By inhibiting HDAC, vorinostat increases the acetylation of histones, regulatory proteins in the cell nucleus that help control DNA transcription. When histones are in their acetylated state, they turn on gene transcription. In tumor cells, this increased transcription leads to cell-cycle arrest and apoptosis. With vorinostat therapy, the most common toxicities are fatigue (52%), diarrhea (52%), nausea (41%), altered taste (28%), anorexia (24%), weight loss (21%), thrombocytopenia (26%), and anemia (14%). Pulmonary embolism (4.7%) is the most common serious effect. Drug interactions have not been studied, but appear to be minimal. Vorinostat is available in 100-mg capsules. The usual dosage is 400 mg once daily.

103.5.6.6 Trastuzumab

Trastuzumab [Herceptin] is a monoclonal antibody directed at HER2, a tyrosine kinase–linked receptor in the same family as the EGFR-tyrosine kinase receptors. The pharmacology of trastuzumab and its use in breast cancer are discussed above.

103.5.7 OTHER NONCYTOTOXIC ANTICANCER DRUGS

103.5.7.1 Retinoids

103.5.7.1.1 Alitretinoin.

Alitretinoin [Panretin] is indicated for topical therapy of *cutaneous lesions* in patients with *AIDS-related Kaposi's sarcoma*. The drug is a retinoid (ie, a derivative of retinol [vitamin A]) that binds to and activates retinoid receptors. In their active state, these receptors regulate the proliferation and differentiation of cells, both normal and neoplastic. When alitretinoin is added to Kaposi's sarcoma cells in culture, it inhibits their growth.

Alitretinoin is supplied as a 0.1% gel for topical use. The drug should be applied only to cutaneous Kaposi's sarcoma lesions, not to normal skin. Following application, the area should dry for 3 to 5 minutes before putting clothing over it. Occlusive dressings should be avoided. Treatment is initiated with twice-daily application. Later on, the drug may be applied 3 or 4 times a day, if tolerance permits. Most patients respond in 4 to 8 weeks. However, some respond in only 2 weeks, and others may not respond until 16 weeks.

Adverse effects are limited to the site of application. Local reactions—erythema, scaling, irritation, rash, and dermatitis—occur in 25% to 77% of patients. The incidence of severe reactions is 10%. Other retinoids are known to cause photosensitivity reactions. Although photosensitivity has not been reported with alitretinoin, exposing the treated area to sunlight or sunlamps should nonetheless be minimized. Retinoids are highly teratogenic. Accordingly, women using alitretinoin should avoid getting pregnant (even though systemic absorption of alitretinoin appears to be minimal).

Alitretinoin is expensive: a 60-gm tube costs over \$2000. However, this is actually cheaper than other treatments for Kaposi's sarcoma.

103.5.7.1.2 Bexarotene.

103.5.7.1.2.1 Mechanism and Use.

Bexarotene [Targretin] is indicated for oral therapy of *cutaneous T-cell lymphoma* in patients who have been refractory to prior systemic therapy. Like alitretinoin, bexarotene is an analog of vitamin A (retinol) and can activate retinoid receptors. The result is altered

regulation of cellular proliferation and differentiation. *In vitro*, bexarotene can inhibit growth of some tumor cell lines. In clinical trials, a dosage of 300 mg/m²/day produced a complete response in 4% of patients, and a partial response (more than 50% improvement) in 48% of patients.

103.5.7.1.2.2 Pharmacokinetics.

Plasma levels peak 2 hours after oral administration. Taking the drug with a high-fat meal increases absorption. Bexarotene undergoes metabolism by CYP3A4 followed by excretion in the bile.

103.5.7.1.2.3 Adverse Effects and Interactions.

Bexarotene causes lipid abnormalities and other serious side effects. In clinical trials, toxicity caused 30% of patients to discontinue treatment.

Major lipid abnormalities are common. Plasma triglycerides rose to a level 2.5 times above the upper limit of the normal range in 70% of patients. Sixty percent of patients had significant elevations in total cholesterol and low-density-lipoprotein cholesterol. Levels of high-density-lipoprotein cholesterol (good cholesterol) were reduced.

Bexarotene frequently causes headache, asthenia, leukopenia, anemia, infection, rash, and photosensitivity. The incidence of clinically significant hypothyroidism is 30%. Fatal pancreatitis and fatal cholestasis have been reported.

Bexarotene and other retinoids are powerful teratogens. Accordingly, bexarotene is absolutely contraindicated for use during pregnancy. Women taking the drug must ensure that pregnancy does not occur.

In theory, drugs that inhibit CYP3A4 can increase bexarotene levels, and drugs that induce CYP3A4 can reduce its levels. Combining vitamin A with bexarotene could result in increased toxicity.

103.5.7.1.3 Tretinoin.

Tretinoin [Vesanoid], also known as all-*trans* retinoic acid (ATRA), is approved for induction of remission in patients with *acute promyelocytic leukemia* (APL). Rates of complete remission are high. Unfortunately, although tretinoin can be very effective, it can

also cause severe toxicity, and hence the benefits of treatment must be carefully weighed against the risks. The mechanism underlying beneficial effects is not well established.

The most common adverse effects are rash, dry skin, and CNS toxicity, manifesting as headache, depression, confusion, and anxiety. The most serious effect, seen in 25% of patients, is *retinoic acid–APL syndrome*, characterized by fever, pleural and pericardial effusions, and hypoxia. In its most severe form, the syndrome can lead to respiratory failure and death. Milder reactions generally respond to high-dose IV glucocorticoids, with no interruption of tretinoin. In severe cases, tretinoin should be withdrawn.

Tretinoin is a substrate for hepatic P450 enzymes, and hence P450 inducers (eg, rifampin, phenytoin, St. John's wort) and inhibitors (eg, erythromycin, azole antifungals, diltiazem) should be avoided.

The recommended dosage is 45 mg/m²/day administered PO as two evenly divided doses. Dosing with food improves absorption.

The use of tretinoin for dermatologic disorders is discussed in [Chapter 104](#).

103.5.7.2 Arsenic Trioxide

Arsenic trioxide [Trisenox] is approved for *acute promyelocytic leukemia* (APL), a rare subtype of acute myelogenous leukemia in which myeloid cells are blocked from undergoing normal differentiation and apoptosis (programmed cell death). In patients who have relapsed following standard therapy of APL, arsenic trioxide has produced a high rate of complete remission. The drug appears to work by reversing the blockade on myeloid differentiation and apoptosis, and by inhibiting angiogenesis.

Toxicity occurs in most patients. Common side effects include nausea, vomiting, diarrhea, fatigue, edema, hyperglycemia, dyspnea, cough, rash, headache, and dizziness. Leukocytosis (elevation of white blood cell counts) occurs in 50% of patients. Of greater concern, about 23% experience a potentially fatal condition known as *APL differentiation syndrome*, characterized by fever, weight gain, pulmonary infiltrates, dyspnea, musculoskeletal pain, and pleural and pericardial effusions. Symptoms can be reduced by immediate therapy with high-dose glucocorticoids. Prolongation of the QT interval is common and can lead to life-threatening dysrhythmias. An electrocardiogram should be obtained prior to treatment and at least weekly thereafter. If possible, drugs known to cause QT prolongation should be withdrawn. Among these are class I and class III antidysrhythmics, clarithromycin, daunorubicin, mesoridazine,

1214

1215

and thioridazine. Arsenic trioxide has the potential to cause fetal harm, and hence is classified in FDA Pregnancy Risk Category D. In contrast to cytotoxic anticancer drugs, arsenic trioxide does not cause alopecia or mucositis.

103.5.7.3 Denileukin Diftitox

103.5.7.3.1 Therapeutic Use.

Denileukin diftitox [Ontak] is an IV drug approved for *cutaneous T-cell lymphoma* (CTCL). In clinical trials, 10% to 16% of patients experienced complete tumor regression, and another 20% to 22% experienced partial regression. Unfortunately, adverse events are very common, and sometimes severe. Denileukin can cause life-threatening hypersensitivity reactions, and hence must be administered in a facility equipped for cardiopulmonary resuscitation.

103.5.7.3.2 Description and Mechanism of Action.

Denileukin is a hybrid molecule consisting of interleukin-2 (IL-2) coupled to diphtheria toxin. The IL-2 portion of the molecule enables it to bind with CTCL cells that have IL-2 receptors. Once the drug is bound, the diphtheria toxin moiety inhibits protein synthesis, causing cell death within hours. Denileukin is produced by recombinant DNA technology.

103.5.7.3.3 Adverse Effects.

In clinical trials, 21% of patients required hospitalization for adverse events. The incidence of severe or life-threatening reactions was 5%.

Acute hypersensitivity reactions occur in 69% of patients. Prominent symptoms are hypotension (50%), back pain (30%), dyspnea (28%), vasodilation (28%), rash (25%), chest pain (24%), and tachycardia (12%). Management consists of stopping the infusion and, if necessary, administering IV epinephrine, antihistamines, and glucocorticoids.

A *flu-like syndrome* occurs in 91% of patients. Symptoms include fever or chills (81%), asthenia (66%), nausea and vomiting (64%), myalgia (18%), and arthralgia (8%). Diarrhea occurs in 29% of patients, and leads to dehydration in 9%.

Denileukin can cause *vascular leak syndrome*, characterized by hypoalbuminemia, edema, and hypotension. Onset usually occurs during the first or second week of treatment. In clinical trials, 6% of patients required hospitalization for the disorder. Because of vascular

leak, hypoalbuminemia occurs in 83% of patients. Serum albumin should be monitored and, if it falls below 3 gm/dL, the next round of treatment should be postponed.

103.5.7.4 Bisphosphonates

As discussed in [Chapter 74](#), bisphosphonates (eg, alendronate, pamidronate) are important drugs for treating osteoporosis and Paget's disease. In addition, evidence indicates that, in women with breast cancer, these drugs can prevent metastases and prolong life. The basic pharmacology of the bisphosphonates is discussed in [Chapter 74](#). Discussion here is limited to their use in cancer.

The anticancer effects of bisphosphonates were discovered somewhat by accident. In women with breast cancer, bisphosphonates were originally employed to suppress bone resorption caused by cancer cells that had metastasized to bone. While using bisphosphonates for this purpose, researchers noted something surprising: Bisphosphonates appeared to reduce the incidence of new bony metastases. Results of a follow-up study confirmed the original observation: In women with breast cancer, treatment with a bisphosphonate reduces metastases to bone and other sites and prolongs survival. These results were obtained using *clodronate*, an oral bisphosphonate available in Europe and Canada. However, other bisphosphonates should also be effective.

How do bisphosphonates suppress metastases? When cancer cells spread to bone, they stimulate the activity of osteoclasts, the cells responsible for bone resorption. In turn, osteoclasts release growth factors that stimulate the cancer cells, thereby setting up a self-reinforcing cycle. Bisphosphonates interrupt the cycle by inhibiting osteoclast function and blocking tumor adhesion to bone.

103.5.7.5 Progestins

Two progestins are employed to treat cancer: *medroxyprogesterone acetate* [Depo-Provera] and *megestrol acetate* [Megace]. Medroxyprogesterone is indicated for *advanced endometrial and renal cancer*. Megestrol is indicated for *advanced endometrial and breast cancer*. In women with metastatic endometrial cancer, progestins promote palliation and tumor regression. About 30% of patients have objective responses. Among those who respond, survival time is increased to about 2 years. This compares with survival times of 6 months among nonresponders. Benefits appear to derive from depriving these cancers of estrogen. How? By inducing enzymes that metabolize estradiol, the primary endogenous estrogen. The

principal adverse effects of progestins are fluid retention and nonfluid weight gain.

Hypercalcemia may occur if bone metastases are present. Progestins may be teratogens, and hence should be avoided during the first 4 months of pregnancy. The basic pharmacology of the progestins is discussed in [Chapter 60](#).

103.5.7.5.1

KEY POINTS

- Nearly all of the anticancer drugs discussed in this chapter—hormonal agents, biologic response modifiers, and targeted drugs—are cell-cycle phase nonspecific, in contrast to many cytotoxic anticancer drugs, which are phase specific.
- Nearly all of the drugs discussed in this chapter lack the characteristic toxicities of the cytotoxic anticancer drugs, including bone marrow suppression, stomatitis, and severe nausea and vomiting. Nonetheless, most can cause severe toxicities of their own.
- Hormonal anticancer drugs act through specific hormone receptors on target tissues. As a result, their actions are fairly selective, and their toxicity to normal cells is generally low.
- Glucocorticoids are toxic to cancers of lymphoid origin, including acute and chronic lymphocytic leukemias, Hodgkin's disease, and non-Hodgkin's lymphomas.
- In addition to their use against lymphoid-derived cancers, glucocorticoids are used to manage complications of cancer and cancer therapy. Specific benefits include suppression of chemotherapy-induced nausea and vomiting, reduction of cerebral edema secondary to irradiation of the cranium, reduction of pain secondary to nerve compression or edema, and suppression of hypercalcemia in steroid-responsive tumors. Also, glucocorticoids can improve appetite and promote weight gain, and may impart a generalized sense of well-being.
- When glucocorticoids are used acutely, their toxicities are both mild and manageable. However, when used long term, these drugs can cause many serious toxicities, including osteoporosis, adrenal insufficiency, increased susceptibility to infection, and peptic ulcers.

<ul style="list-style-type: none"> ▪ Advanced prostate cancer is treated with androgen deprivation, which can be achieved with castration or drug therapy. Early (localized) prostate cancer is treated with surgery or radiation, sometimes followed by androgen deprivation. ▪ Androgen deprivation can be achieved with two types of drugs: gonadotropin-releasing hormone (GnRH) agonists and androgen receptor blockers. ▪ Leuprolide, a GnRH agonist, has a biphasic mechanism of action. During the initial phase, the drug stimulates release of interstitial cell–stimulating hormone (ICSH) from the pituitary, and thereby increases production of testosterone by the testes. As 	<p>1215</p> <p>1216</p>
<p>a result, there may be a transient “flare” in prostate cancer symptoms. With continuous use, the drug suppresses ICSH release, and thereby causes testosterone production to fall. It is important to note that leuprolide does not decrease production of adrenal androgens.</p> <ul style="list-style-type: none"> ▪ Flutamide, an androgen receptor blocker, is used in combination with a GnRH agonist to treat prostate cancer. Benefits derive from (1) preventing cancer cells from undergoing increased stimulation during the initial phase of GnRH therapy, and (2) blocking the effects of adrenal androgens on prostate cells. ▪ Breast cancer is treated with surgery, radiation, cytotoxic drugs, and hormonal agents, of which there are two major groups: antiestrogens and aromatase inhibitors. ▪ Antiestrogens block estrogen receptors, whereas aromatase inhibitors block estrogen synthesis. For either group to work, the cancer must be ER positive. ▪ Antiestrogens fall into two major categories: (1) pure estrogen receptor antagonists and (2) SERMs, which block estrogen receptors in some tissues, and activate estrogen receptors in others. ▪ Tamoxifen, a SERM, is approved for prevention and treatment of breast cancer. Benefits derive from blocking estrogen receptors on tumor cells. The drug is not active against cancers that are ER negative. ▪ Like tamoxifen, raloxifene (a SERM) decreases the risk of breast cancer. Compared with tamoxifen, raloxifene carries a lower risk of uterine cancer, and hence appears safer than tamoxifen for breast cancer prevention. 	

- By activating certain estrogen receptors, tamoxifen increases the risk of endometrial cancer and thromboembolism.
- Fulvestrant, a pure estrogen receptor antagonist, is approved for treatment of breast cancer, but not for prevention.
- In contrast to tamoxifen and other SERMs, fulvestrant poses no risk of endometrial cancer, and only a slight risk of thromboembolism.
- Anastrozole, an aromatase inhibitor, is used to treat ER-positive breast cancer in postmenopausal women only. Benefits derive from preventing production of estrogen from adrenal androgens.
- Anastrozole is more effective than tamoxifen and poses no risk of endometrial cancer. However, it can cause osteoporosis and fractures, and (rarely) thromboembolism.
- In addition to antiestrogens and aromatase inhibitors, breast cancer can be treated with trastuzumab, a monoclonal antibody that binds with HER2, and thereby inhibits cell proliferation and promotes immune-mediated cell death.
- The major adverse effect of trastuzumab is cardiac injury, manifesting as ventricular dysfunction and heart failure.
- Interferon alfa, a biologic response modifier, benefits cancer patients by enhancing immune responses and suppressing cancer cell proliferation.
- Targeted anticancer drugs are designed to bind with specific molecules (targets) that drive tumor growth. If the target molecules are found only (or mainly) on cancer cells, targeted drugs should be able to arrest tumor growth while causing little or no injury to normal cells. The current reality, however, is that most targeted drugs cause serious adverse effects.
- Many targeted drugs are monoclonal antibodies directed at antigens found primarily on cancer cells. Most other targeted drugs are small molecules that inhibit specific tyrosine kinases that regulate cell proliferation.

- EGFR-TK (epidermal growth factor receptor linked with tyrosine kinase), a regulatory molecule found in certain normal cells and many cancer cells, plays an important role in regulating cell proliferation.
- Cetuximab is a monoclonal antibody that blocks the receptor portion of EGFR-TK, and thereby suppresses cell growth and promotes apoptosis.
- Cetuximab can cause severe infusion reactions and severe acne-like rash.
- Like cetuximab, gefitinib inhibits EGFR-TK. However, in contrast to cetuximab, gefitinib is a small molecule (rather than an antibody) that works inside the cell to directly inhibit TK (rather than outside the cell to block EGFR).
- The CD20 antigen is a molecule present in the cell membrane of normal and malignant B lymphocytes (B cells).
- Rituximab is a monoclonal antibody that binds with CD20, and thereby initiates apoptosis plus a lethal immune attack on B cells. The drug is indicated only for B-cell non-Hodgkin's lymphoma.
- Rituximab can cause severe infusion-related hypersensitivity reactions.
- Angiogenesis inhibitors block growth of new blood vessels needed to supply solid tumors with oxygen and nutrients.
- Because angiogenesis inhibitors affect blood vessels rather than specific cancer cells, they should be active against a wide variety of tumors.
- Bevacizumab is a monoclonal antibody that binds with VEGF (vascular endothelial growth factor), and thereby prevents VEGF from promoting blood vessel formation. By suppressing angiogenesis, bevacizumab can inhibit further tumor growth, but cannot directly kill existing tumor cells.
- Bevacizumab can cause hypotension, GI perforation, impaired wound healing, and thromboembolism.
- Proteasomes are multienzyme complexes that degrade intracellular proteins, and thereby rid cells of proteins that are not currently needed, including proteins that

regulate transcription, cell adhesion, apoptosis, and progression through the cell cycle.

- Bortezomib, a proteasome inhibitor, reduces cell viability, increases apoptosis, and increases sensitivity to the lethal effects of radiation and traditional anticancer drugs.
- Bortezomib can cause bone marrow suppression, GI disturbances, and peripheral neuropathy.
- Cells of chronic myeloid leukemia (CML) produce an abnormal, continuously active enzyme—BCR-ABL tyrosine kinase—that activates regulatory proteins, which in turn inhibit apoptosis and stimulate excessive cell proliferation.
- Imatinib is a highly specific competitive inhibitor of BCR-ABL tyrosine kinase. In patients with CML, the drug suppresses cell proliferation and promotes apoptosis.
- Imatinib can be considered the model of a successful targeted anticancer drug, being both highly effective and well tolerated. The drug is the current standard of care for CML.

¹⁰⁴CHAPTER 103 Drugs for the Eye

The drugs addressed in this chapter are used to diagnose and treat disorders of the eye. Our primary focus is on glaucoma. Many of the drugs considered here are discussed at length in other chapters. Accordingly, discussion here is limited to their ophthalmologic applications.

^{10...}DRUGS FOR GLAUCOMA

The term *glaucoma* refers to a group of diseases characterized by visual field loss secondary to optic nerve damage. The most common forms of glaucoma are primary open-angle glaucoma and acute angle-closure glaucoma. These forms differ with respect to underlying pathology and treatment. With either form, permanent blindness can result.

In the United States, glaucoma is the leading cause of preventable blindness. Of the 120,000 Americans blinded by glaucoma, 90% could have saved their sight with timely treatment. Unfortunately, many afflicted persons are unaware of their condition: Of the 4 million Americans with glaucoma, only 50% are diagnosed.

Before discussing glaucoma, we need to review the role of aqueous humor in maintaining intraocular pressure (IOP). As indicated in [Figure 103-1](#), aqueous humor is produced by the ciliary body and secreted into the posterior chamber of the eye. From there it circulates around the iris into the anterior chamber, and then exits the anterior chamber via the trabecular meshwork and canal of Schlemm. If outflow from the anterior chamber is impeded, back-pressure will develop, and IOP will rise. Conversely, if production of aqueous humor falls, IOP will decline.

^{104.1.1}Pathophysiology and Treatment Overview

^{104.1.1.1}Primary Open-Angle Glaucoma

^{104.1.1.1.1}Characteristics.

Primary open-angle glaucoma (POAG) is the most common form of glaucoma in the United States. About 90% of people with glaucoma have this type. POAG is the leading cause of blindness among African Americans and the third leading cause among whites.

POAG is characterized by progressive optic nerve damage with eventual impairment of vision. Visual loss develops first in the peripheral visual field. As the disease advances, loss

Figure 103-1 Anatomy of the normal eye.

1217

occurs in the central visual field. The pathologic process that leads to optic nerve damage is not understood. IOP is often elevated, but it may also be normal. POAG is a painless, insidious disease in which injury develops over years. Symptoms are absent until extensive optic nerve damage has been produced.

1218

104.1.1.1.2 Risk Factors.

The major risk factors for POAG are

- Elevation of IOP
- Black race
- Family history of POAG
- Advancing age

Of these, elevated IOP is most important. Please note, however, that glaucomatous optic nerve damage can develop even when IOP is normal (ie, below 20 mm Hg). Furthermore, some individuals can have very high IOP (eg, 30 mm Hg) with no associated injury to the optic nerve. These individuals are said to have *ocular hypertension*—not glaucoma.

Among African Americans, the incidence of POAG is 3 times higher than among whites. Also, the age of onset is lower and the course of the disease is more aggressive.

104.1.1.1.3 Screening.

Since POAG is devoid of symptoms (until significant and irreversible optic nerve injury has occurred), regular testing for early POAG is important—especially among individuals at high risk. With early detection and treatment, blindness can usually be prevented. Diagnosis is based on glaucomatous optic nerve atrophy in association with a characteristic reduction in peripheral vision. Individuals with risk factors for POAG should be tested every 2 years up to age 45, and yearly thereafter. Individuals without risk factors should be tested every 4 years up to age 45, and every 2 years thereafter.

104.1.1.1.4 Management.

Treatment of POAG is directed at reducing elevated IOP, the only risk factor we can modify. Although POAG has no cure, reduction of IOP can slow or even stop disease progression.

The principal method for reducing IOP is chronic therapy with drugs. Drugs lower IOP by either (1) facilitating aqueous humor outflow or (2) reducing aqueous humor production. As indicated in [Table 103-1](#), the first-line drugs for glaucoma belong to three classes: *beta-adrenergic blocking agents* (beta blockers), *alpha₂-adrenergic agonists*, and *prostaglandin analogs*. Other options—*cholinergic agonists*, *carbonic anhydrase inhibitors*, and *nonselective adrenergic agonists*—are considered second-line choices. All of the antiglaucoma drugs are available for topical administration, the preferred route. For more than 20 years, the beta blockers (eg, timolol) have been considered drugs of first choice. However, the alpha₂ agonists (eg, brimonidine) and prostaglandin analogs (eg, latanoprost) are just as effective as the beta blockers, and have a more desirable side effect profile. Accordingly, these drugs have joined the beta blockers as first-choice agents. Because drugs in different classes lower IOP by different mechanisms, combined therapy can be more effective than monotherapy. Because all of these drugs are applied topically, systemic effects are relatively uncommon. Nonetheless, serious systemic reactions *can* occur if sufficient absorption takes place.

1218

1219

TABLE 103-1 Topical Drugs for Open-Angle Glaucoma

Class	Drugs	Mechanism	Adverse Effects
First-Line Agents			
Beta Blockers			
Nonselective	Timolol	Decreased aqueous formation	Heart block, bradycardia, bronchospasm
	Carteolol		
	Levobunolol		
	Metipranolol		
Beta ₁ selective	Betaxolol		Heart block, bradycardia, hypotension
	Levobetaxolol		
Alpha ₂ -Adrenergic Agonists	Apraclonidine*	Decreased aqueous formation	Headache, dry mouth, dry nose, altered taste, conjunctivitis, lid reactions, pruritus
	Brimonidine		
Prostaglandin Analogs	Latanoprost	Increased aqueous outflow	Heightened brown pigmentation of the iris and eyelid
	Travoprost		
	Bimatoprost		
	Unoprostone		
Second-Line Agents			
Cholinergic Agonists			
Direct acting	Pilocarpine	Increased aqueous outflow	Miosis, blurred vision
Acetylcholinesterase inhibitors	Echothiophate		
Carbonic Anhydrase Inhibitors	Dorzolamide	Decreased aqueous formation	Ocular stinging, bitter taste, conjunctivitis, lid reactions
	Brinzolamide		
Nonselective Adrenergic Agonists	Dipivefrin†	Increased aqueous outflow	Mydriasis, tachycardia, hypertension

* Apraclonidine is indicated for short-term use only, and hence is *not* a first-line drug for glaucoma.

† Dipivefrin is converted to epinephrine in the eye.

If drugs are unable to reduce IOP to an acceptable level, surgical intervention to promote outflow of aqueous humor is indicated. Options include laser trabeculoplasty and trabeculectomy (done with conventional surgical techniques).

104.1.1.2 Angle-Closure Glaucoma

Angle-closure glaucoma is precipitated by displacement of the iris such that it covers the trabecular meshwork, thereby preventing exit of aqueous humor from the anterior chamber. As a result, IOP increases rapidly and to dangerous levels. This disorder is referred to as *angle-closure* or *narrow-angle* glaucoma because the angle between the cornea and the iris is greatly reduced ([Fig. 103-2](#)). Angle-closure glaucoma develops suddenly and is extremely painful. In the absence of treatment, irreversible loss of vision occurs in 1 to 2 days. This disorder is much less common than open-angle glaucoma.

Treatment consists of *drug therapy* (to control the acute attack) followed by *corrective surgery*. A combination of drugs (osmotic agents, short-acting miotics, carbonic anhydrase inhibitors, topical beta-adrenergic blocking agents) is employed to suppress symptoms. Once IOP has been reduced with drugs, definitive treatment can be rendered with surgery. Options include *laser iridotomy* and *iridectomy* performed by conventional surgery. Both procedures alter the iris to permit unimpeded outflow of aqueous humor.

104.1.2 Drugs Used to Treat Glaucoma

104.1.2.1 Beta-Adrenergic Blocking Agents

104.1.2.1.1 Actions and Use in Glaucoma.

Six beta blockers—*betaxolol*, *levobetaxolol*, *carteolol*, *levobunolol*, *metipranolol*, and *timolol*—are approved for use in glaucoma. Administration is topical. These agents cause minimal disturbance of vision and are considered first-line drugs for glaucoma (although prostaglandin analogs are becoming favored). Formulations and dosages of the beta blockers are summarized in [Table 103-2](#).

The beta-adrenergic blockers lower IOP by decreasing production of aqueous humor. Reductions in IOP occur with “nonselective” beta blockers (drugs that block beta₁ and beta₂ receptors) as well as with “cardioselective” beta blockers (drugs that block beta₁ receptors only).

Beta blockers are used primarily for open-angle glaucoma. They are suitable for initial therapy as well as maintenance therapy. Beta blockers (in combination with other drugs) are also employed for emergency management of acute angle-closure glaucoma.

The basic pharmacology of the beta blockers is discussed in [Chapter 18](#).

104.1.2.1.2 Adverse Effects.

104.1.2.1.2.1 Local.

Local effects are generally minimal, although patients commonly complain of transient ocular stinging. Beta blockers occasionally cause conjunctivitis, blurred vision, photophobia, and dry eyes.

104.1.2.1.2.2 Systemic.

Beta blockers can be absorbed in amounts sufficient to cause systemic effects. Effects on the heart and lungs are of greatest concern.

Figure 103-2 Comparative anatomy of the eye in open-angle and angle-closure glaucoma. **A** Note that the angle between the iris and cornea is open in open-angle glaucoma, permitting unimpeded outflow of aqueous humor through the canal of Schlemm and trabecular meshwork. **B** Note that the angle between the iris and cornea is constricted in angle-closure glaucoma, thereby blocking outflow of aqueous humor through the canal of Schlemm and trabecular meshwork.

TABLE 103-2 Beta Blockers Used in Glaucoma

Drug	Receptor Specificity	Formulation	Usual Dosage
Betaxolol [Betoptic, Betoptic S]	Beta ₁	0.25% suspension	1 drop twice a day
		0.5% solution	1 drop twice a day
Levobetaxolol [Betaxon]	Beta ₁	0.5% suspension	1 drop twice a day
Carteolol [Ocupress]	Beta ₁ , beta ₂	1% solution	1 drop twice a day
Levobunolol [Betagan Liquifilm, AKBeta]	Beta ₁ , beta ₂	0.25% solution	1 drop twice a day
		0.5% solution	1 drop once or twice a day
Metipranolol [OptiPranolol]	Beta ₁ , beta ₂	0.3% solution	1 drop twice a day
Timolol [Timoptic, Betimol Istalol]	Beta ₁ , beta ₂	0.25% solution	1 drop once or twice a day
		0.5% solution	1 drop once or twice a day
		0.25% gel	1 drop once a day
		0.5% gel	1 drop once a day

Blockade of cardiac beta₁ receptors can produce bradycardia and atrioventricular (AV) heart block. Pulse rate should be monitored. Because of their ability to depress cardiac function, beta blockers are contraindicated for patients with AV heart block, sinus bradycardia, and cardiogenic shock. In addition, they should be used with caution in patients with heart failure.

Blockade of beta₂ receptors in the lung can cause bronchospasm. Constriction of the bronchi can occur with “beta₁selective” antagonists as well as with “nonselective” betaadrenergic blockers—although the risk is greatest with the nonselective agents. Only two ophthalmic beta blockers—betaxolol and levobetaxolol—are beta₁ selective, and hence are preferred for patients with asthma or chronic obstructive pulmonary disease.

104.1.2.2 Prostaglandin Analogs

Four prostaglandin analogs are approved for topical therapy of glaucoma. These drugs are as effective as the beta blockers and cause fewer side effects. Accordingly, they are considered first-line medications for glaucoma. Formulations and dosages are summarized in [Table 103-3](#).

104.1.2.2.1 Latanoprost.

Latanoprost [Xalatan], an analog of prostaglandin F₂ alpha, was the first prostaglandin approved for glaucoma and will serve as our prototype for the group. The drug is applied topically to lower IOP in patients with open-angle glaucoma and ocular hypertension. Latanoprost lowers IOP by facilitating aqueous humor outflow, in part by relaxing the ciliary muscle. The recommended dosage is 1 drop (0.005% solution) applied once daily in the evening. At this dosage, latanoprost produces the same reduction in IOP as timolol twice daily.

Latanoprost is generally well tolerated, and systemic reactions are rare. The most significant side effect is a harmless heightened brown pigmentation of the iris. This is most noticeable in patients whose irides are green-brown, yellow-brown, or blue/gray-brown. The effect is rare in patients whose irides are blue, green, or blue-green. Heightened pigmentation stops progressing when latanoprost is discontinued, but does not usually regress. Topical latanoprost may also increase pigmentation of the eyelid, and increase growth and pigmentation of the eyelashes. Other side effects include blurred vision, burning, stinging, conjunctival hyperemia, and punctate keratopathy. Rarely, the drug may cause migraine.

104.1.2.2.2 Other Prostaglandin Analogs.

In addition to latanoprost, two other topical prostaglandins are approved for topical therapy of glaucoma. Like latanoprost, these drugs—*travoprost* [Travatan], and *bimatoprost* [Lumigan], reduce IOP by increasing aqueous humor outflow. In clinical trials, these agents were at least as effective as timolol, a representative beta blocker. Interestingly, one drug—travoprost—was more effective in African Americans than in non-African Americans. Like latanoprost, these prostaglandins can cause a gradual increase in brown pigmentation of the iris, which may be irreversible. In addition, they may increase pigmentation of the eyelid and growth of the eyelashes. Their most common adverse effect is ocular hyperemia. Less commonly, they may cause blurred vision, eye discomfort, ocular pruritus, conjunctivitis, dry eye, light intolerance, and tearing. Dosages are summarized in [Table 103-3](#).

104.1.2.3 Alpha₂-Adrenergic Agonists

Two alpha₂ agonists are approved for glaucoma. One agent—apraclonidine—is used only for short-term therapy. The other agent—brimonidine—has emerged as a first-line drug for long-term therapy.

104.1.2.3.1 Brimonidine.

Brimonidine [Alphagan] is the first and only topical α_2 -adrenergic agonist approved for *long-term* reduction of elevated IOP in patients with open-angle glaucoma or ocular hypertension. The recommended dosage is 1 drop 3 times a day. Effects on IOP are similar to those achieved with timolol. The drug lowers IOP by reducing aqueous humor production, and perhaps by increasing outflow. In addition to lowering IOP, brimonidine may be able to delay optic nerve degeneration and may protect retinal neurons from death. This possibility arises from the ability of α_2 agonists to protect neurons from injury caused by ischemia. The drug's most common adverse effects are dry mouth, ocular hyperemia (engorgement of ocular blood vessels), local burning and stinging, headache, blurred vision, foreign body sensation, and ocular itching. In contrast to apraclonidine (see below), brimonidine can cross the blood-brain barrier, and hence can cause drowsiness, fatigue, and hypotension. (Recall from [Chapter 19](#) that activation of α_2 receptors in the brain decreases sympathetic outflow to blood vessels, and thereby lowers blood pressure.) Brimonidine can be absorbed onto soft contact lenses. Accordingly, at least 15 minutes should elapse between drug administration and lens installation.

TABLE 103-3 Prostaglandin Analogs Used in Glaucoma

Generic Name	Trade Name	Formulation	Usual Dosage
Latanoprost	Xalatan	0.005% solution	1 drop once daily in the evening
Travoprost	Travatan	0.004% solution	1 drop once daily in the evening
Bimatoprost	Lumigan	0.03% solution	1 drop once daily in the evening

104.1.2.3.2 Apraclonidine.

Apraclonidine [Iopidine], a topical α_2 -adrenergic agonist, lowers IOP by reducing aqueous humor production and possibly by increasing outflow. The drug is indicated only for (1) short-term therapy of open-angle glaucoma in patients who have not responded adequately to maximal doses of other IOP-lowering drugs, and (2) preoperative medication prior to laser trabeculoplasty or iridotomy. Side effects include headache, dry mouth, dry nose, altered taste, conjunctivitis, lid reactions, pruritus, tearing, and blurred vision. Apraclonidine does not cross the blood-brain barrier, and hence does not promote hypotension. For short-term therapy of glaucoma, the dosage is 1 or 2 drops (0.5% solution) 3 times a day.

104.1.2.4 Alpha₂ Agonist/Beta Blocker Combination

In 2007, the Food and Drug Administration approved a fixed-dose combination of brimonidine (an alpha₂ agonist) and timolol (a nonselective beta blocker) for lowering IOP in patients with glaucoma or ocular hypertension. The combination, sold as *Combigan*, contains 0.2% brimonidine and 0.5% timolol. Treatment consists of 1 drop applied to the affected eye twice daily (about every 12 hours). Benefits and adverse effects are about equal to those seen when the two drugs are applied separately.

104.1.2.5 Pilocarpine, a Direct-Acting Cholinergic Agonist

Pilocarpine is a direct-acting muscarinic agonist (parasympathomimetic agent). Administration is topical. The basic pharmacology of the muscarinic agonists is discussed in [Chapter 14](#). Consideration here is limited to the use of pilocarpine in glaucoma.

104.1.2.5.1 Effects on the Eye.

By stimulating cholinergic receptors in the eye, pilocarpine produces two direct effects: (1) *miosis* (constriction of the pupil secondary to contraction of the iris sphincter), and (2) *contraction of the ciliary muscle* (an action that focuses the lens for near vision). IOP is lowered indirectly. In patients with *open-angle glaucoma*, IOP is reduced because the tension generated by contracting the ciliary muscle promotes widening of the spaces within the trabecular meshwork, thereby facilitating outflow of aqueous humor. In *angle-closure glaucoma*, contraction of the iris sphincter pulls the iris away from the pores of the trabecular meshwork, thereby removing the impediment to aqueous humor outflow.

104.1.2.5.2 Therapeutic Uses.

Although used widely in the past, pilocarpine is now considered a second-line drug for open-angle glaucoma. Pilocarpine can also be used for emergency treatment of acute angle-closure glaucoma.

104.1.2.5.3 Adverse Effects.

The major side effects of pilocarpine concern the eye. Contraction of the ciliary muscle focuses the lens for near vision; corrective lenses can provide partial compensation for this problem. Occasionally, sustained contraction of the ciliary muscle causes retinal detachment. Constriction of the pupil, caused by contraction of the iris sphincter, may decrease visual acuity. Pilocarpine may also produce local irritation, eye pain, and brow ache.

Rarely, pilocarpine is absorbed in amounts sufficient to cause systemic effects. Stimulation of muscarinic receptors throughout the body can produce a variety of responses, including bradycardia, bronchospasm, hypotension, urinary urgency, diarrhea, hypersalivation, and sweating. Caution should be exercised in patients with asthma or bradycardia. Systemic toxicity can be reversed with a muscarinic antagonist (eg, atropine).

104.1.2.5.4 Preparations, Dosage, and Administration.

Pilocarpine is available in solution and a gel for topical use; an “ocular system,” known as *Ocusert*, has been withdrawn. Pilocarpine solutions have a relatively short duration of action and must be administered more frequently than the gel.

104.1.2.5.4.1 Pilocarpine Solutions.

Pilocarpine hydrochloride [Adorbocarpine, Akarpine, Isopto Carpine, Pilocar, Piloptic, Pilostat] is available in solution for topical application to the conjunctiva. Concentrations range from 0.25% to 10%. For maintenance therapy of open-angle glaucoma, the usual dosage is 1 drop of solution (0.5% to 4%) applied 4 times a day. For patients with acute angle-closure glaucoma, pilocarpine is applied much more frequently (eg, every 5 to 10 minutes for three to six doses, then 1 drop every 1 to 3 hours).

104.1.2.5.4.2 Pilocarpine Gel.

Pilocarpine ophthalmic gel [Pilopine HS] consists of 4% pilocarpine hydrochloride in an aqueous gel base. The preparation has a long duration of action, making once-a-day dosing sufficient. For chronic open-angle glaucoma, the usual dosage is ½ inch of gel applied to the conjunctiva at bedtime.

104.1.2.6 Cholinesterase Inhibitor: Echothiophate, an Indirect-Acting Cholinergic Agonist

Only one cholinesterase inhibitor—echothiophate [Phospholine Iodide]—is available for treating glaucoma. The drug has a long duration of action. The basic pharmacology of echothiophate and other cholinesterase inhibitors is discussed in [Chapter 15](#). Consideration here is limited to its use in glaucoma.

104.1.2.6.1 Effects on the Eye.

Cholinesterase inhibitors inhibit breakdown of acetylcholine (ACh), and thereby promote accumulation of ACh at muscarinic receptors. As a result, they can produce the same ocular effects as pilocarpine (ie, miosis, focusing of the lens for near vision, reduction of IOP).

104.1.2.6.2 Use in Glaucoma.

Echothiophate is indicated for POAG. However, because of concerns about adverse effects, the drug is not a first-choice agent. Rather, it is reserved for patients who have responded poorly to preferred medications (eg, beta blockers, alpha₂ agonists, prostaglandins).

104.1.2.6.3 Adverse Effects.

Like pilocarpine, echothiophate can cause *myopia* (secondary to contraction of the ciliary muscle) and excessive pupillary constriction. However, of much greater concern is the association between long-acting cholinesterase inhibitors and development of cataracts. Absorption of echothiophate into the systemic circulation can produce typical *parasympathomimetic responses*, including bradycardia, bronchospasm, sweating, salivation, urinary urgency, and diarrhea.

104.1.2.6.4 Preparations, Dosage, and Administration.

Echothiophate iodide [Phospholine Iodide] is supplied as a powder for reconstitution to solutions that range in strength from 0.03% to 0.25%. For open-angle glaucoma, the 0.03% solution is commonly employed. Administration into the conjunctival sac may be done once daily, twice daily, or every other day.

104.1.2.7 Dipivefrin

Dipivefrin [AKPRO, Propine] is a prodrug form of *epinephrine*, an adrenergic agonist that activates alpha- and beta-adrenergic receptors. Once in the eye, dipivefrin is converted to epinephrine by ocular enzymes. Because of its high lipid solubility, dipivefrin penetrates the cornea more readily than does epinephrine itself, and hence has replaced epinephrine for topical therapy of glaucoma. Because epinephrine is the active form of dipivefrin, the term *epinephrine* rather than *dipivefrin* is used throughout the following discussion. The basic pharmacology of epinephrine is discussed in [Chapter 17](#).

104.1.2.7.1 Actions and Uses in Glaucoma.

Epinephrine is used for open-angle glaucoma. The drug reduces IOP apparently by increasing aqueous humor outflow. The mechanism by which outflow is enhanced is not fully understood. Epinephrine may be used alone and in combination with other antiglaucoma drugs.

104.1.2.7.2 Adverse Effects.

Mild reactions—headache, brow ache, blurred vision, and ocular irritation—are relatively common. By contracting the radial muscle of the iris, epinephrine can cause mydriasis (pupil dilation) and thereby can aggravate angle-closure glaucoma. Accordingly, epinephrine is contraindicated for patients with this disorder. In the patient whose lens has been removed, epinephrine can cause an unusual edema of the retina. This reaction is reversed when treatment stops. Systemic absorption can cause tachycardia and elevation of blood pressure; caution should be exercised in patients with hypertension, dysrhythmias, and hyperthyroidism (hyperthyroidism sensitizes the heart to stimulation by catecholamines).

104.1.2.7.3 Preparations, Dosage, and Administration.

Dipivefrin [Propine, AKPro] is available in a 0.1% solution. For open-angle glaucoma, 1 drop is instilled into the conjunctival sac every 12 hours.

1221

104.1.2.8 Carbonic Anhydrase Inhibitors: Topical

1222

104.1.2.8.1 Dorzolamide.

Introduced in 1995, dorzolamide [Trusopt] was the first carbonic anhydrase inhibitor available for topical administration. The drug is used to reduce IOP in patients with open-angle glaucoma and ocular hypertension. Dorzolamide lowers IOP by decreasing production of aqueous humor. The recommended dosage is 1 drop (2% solution) 3 times a day. Responses are similar to those produced with beta blockers.

Dorzolamide is generally well tolerated. The most common side effects are ocular stinging and bitter taste immediately after dosing. Between 10% and 15% of patients experience allergic reactions, primarily conjunctivitis and lid reactions. If these occur, the patient should stop dorzolamide and contact the prescriber. Other reactions include blurred vision, tearing, eye dryness, and photophobia. In contrast to systemic carbonic anhydrase inhibitors, dorzolamide does not produce acidosis or electrolyte imbalance.

Dorzolamide is also available in a fixed-dose combination with timolol, marketed as *Cosopt*. The combination produces a greater reduction in IOP than either component used alone. The recommended dosage is 1 drop twice a day.

104.1.2.8.2 Brinzolamide.

Brinzolamide [Azopt] was approved in 1998 for topical treatment of elevated IOP in patients with open-angle glaucoma or ocular hypertension. The drug is as effective as dorzolamide and better tolerated. Like other carbonic anhydrase inhibitors, brinzolamide reduces IOP by slowing production of aqueous humor. The most common adverse effects are bitter aftertaste and transient blurred vision. Brinzolamide causes less ocular stinging and burning than dorzolamide. The recommended dosage is 1 drop (1% solution) 3 times a day.

104.1.2.9 Carbonic Anhydrase Inhibitors: Systemic

Two carbonic anhydrase inhibitors—*acetazolamide* and *methazolamide*—are available for systemic therapy of glaucoma. Acetazolamide is used more often.

104.1.2.9.1 Actions and Uses in Glaucoma.

Carbonic anhydrase inhibitors lower IOP by decreasing production of aqueous humor. Maximally effective doses reduce aqueous flow by 50%. Administration is oral.

Carbonic anhydrase inhibitors are employed primarily for long-term treatment of open-angle glaucoma. They are not drugs of first choice. Rather, they should be reserved for patients who have been refractory to preferred medications (eg, beta blockers, α_2 agonists, prostaglandin analogs). Carbonic anhydrase inhibitors may also be given (in combination with other antiglaucoma drugs) to produce rapid lowering of IOP in patients with angle-closure glaucoma.

104.1.2.9.2 Adverse Effects.

Systemic carbonic anhydrase inhibitors can produce multiple adverse effects. Effects on the central nervous system, which are relatively common, include malaise, anorexia, fatigue, and paresthesias. The sense of malaise causes many patients to discontinue treatment. Reduced appetite, coupled with GI disturbances (nausea, vomiting, diarrhea), may result in weight loss. Carbonic anhydrase inhibitors are teratogenic in animals and should be avoided during pregnancy, especially the first trimester. Additional concerns are acid-base disturbances, electrolyte imbalance, and nephrolithiasis (formation of renal calculi).

104.1.2.9.3 Preparations, Dosage, and Administration.

Acetazolamide is available in tablets (125 and 250 mg) and 500-mg sustained-release capsules (sold as Diamox Sequels), and in solution (500 mg/vial) for IM and IV administration. The usual dosage range is 250 mg to 1 gm/day in divided doses.

Methazolamide is available in 25- and 50-mg oral tablets. The usual dosage is 50 to 100 mg 2 or 3 times a day.

104.1.2..... Osmotic Agents

Four osmotic agents—*mannitol*, *urea*, *glycerin*, and *isosorbide*—are employed in glaucoma. These agents render the plasma hypertonic to intraocular fluid and thereby draw water from the eye. The result is a rapid and marked reduction of IOP. The principal indication for osmotic agents is emergency treatment of acute angle-closure glaucoma. Use in open-angle glaucoma is limited to the perioperative period. Glycerin and isosorbide are administered PO; mannitol and urea are administered by IV infusion. Doses for these drugs range from 0.5 to 2 gm/kg. Common side effects are headache, nausea, and vomiting. The use of mannitol for osmotic diuresis is discussed in [Chapter 40](#).

10... CYCLOPLEGICS AND MYDRIATICS

Cycloplegics are drugs that paralyze the ciliary muscle, and *mydriatics* are drugs that dilate the pupil. Cycloplegics and mydriatics are employed primarily to facilitate diagnosis and surgery of ophthalmic disorders. Agents used to produce cycloplegia, mydriasis, or both fall into two classes: (1) *anticholinergic agents* (muscarinic antagonists) and (2) *adrenergic agonists*.

104.2.1 Anticholinergic Agents

Several muscarinic antagonists ([Table 103-4](#)) are employed topically for diagnosis and treatment of ophthalmic disorders. The basic pharmacology of the anticholinergic drugs is discussed in [Chapter 14](#). Consideration here is limited to ophthalmic applications.

104.2.1.1 Effects on the Eye

The anticholinergic drugs produce mydriasis and cycloplegia. Mydriasis results from blocking muscarinic receptors that promote contraction of the iris sphincter; cycloplegia results from blocking muscarinic receptors that promote contraction of the ciliary muscle. As discussed below, relaxation of the iris can lead to elevation of IOP.

104.2.1.1.1 Ophthalmic Applications

104.2.1.1.1.1 Adjunct to Measurement of Refraction.

The term *refraction* refers to the bending of light by the cornea and lens. When ocular refraction is proper, incoming light is bent such that a sharp image is formed on the retina. Errors in refraction can produce nearsightedness, farsightedness, and astigmatism (a visual disturbance caused by irregularities in the curvature of the cornea).

TABLE 103-4 Muscarinic Antagonists Used for Mydriasis and Cycloplegia

Generic Name	Trade Name	Strength of Solution (%)	Time Course			
			Mydriasis		Cycloplegia	
			Peak (min)	Recovery (days)	Peak (min)	Recovery (days)
Atropine	Isopto Atropine	0.5, 1, 2	30–40	7–12	60–180	6–12
Cyclopentolate	AK-Pentolate Cyclogyl	0.5, 1, 2	30–60	1	25–76	0.25–1
Homatropine	Isopto Homatropine	2, 5	40–60	1–3	30–60	1–3
Scopolamine	Isopto Hyoscine	0.25	20–30	1–3	30–60	3–7
Tropicamide	Mydriacyl Tropicacyl Opticyl	0.5, 1	20–40	0.25	20–35	<0.25

Both the mydriatic and cycloplegic properties of the muscarinic antagonists can be of use in evaluating errors of refraction. Mydriasis (widening of the pupil) facilitates observation of the eye's interior. Cycloplegia (paralysis of the ciliary muscle) prevents the lens from undergoing changes in configuration during the assessment.

104.2.1.1.1.2 Intraocular Examination.

Dilation of the pupil with an anticholinergic agent facilitates observation of the inside of the eye. In addition, by paralyzing the iris sphincter, muscarinic antagonists prevent reflexive constriction of the pupil in response to the light from an ophthalmoscope (the hand-held device used to view the eye's interior). Since adrenergic agonists (eg, phenylephrine) also dilate the pupil, but by a different mechanism, an adrenergic agonist can be combined with a muscarinic antagonist to increase the degree of mydriasis.

104.2.1.1.1.3 Intraocular Surgery.

Anticholinergic agents may be employed to facilitate ocular surgery and to reduce postoperative complications. Mydriasis induced by these drugs can aid in cataract extraction and procedures to correct retinal detachment. For these operations, the muscarinic antagonist may be combined with an adrenergic agonist to maximize pupillary dilation. In certain postoperative patients, mydriatics are employed to prevent development of synechiae (adhesions of the iris to neighboring structures in the eye).

104.2.1.1.1.4 Treatment of Anterior Uveitis.

Uveitis is an inflammation of the uvea (the vascular layer of the eye). Symptoms include ocular pain and photophobia. Uveitis is treated with a glucocorticoid (to reduce inflammation) plus an anticholinergic agent. By promoting relaxation of the ciliary muscle and the iris sphincter, anticholinergic drugs help relieve pain and prevent adhesion of the iris to the lens.

104.2.1.1.2 Adverse Effects

104.2.1.1.2.1 Blurred Vision and Photophobia.

The most common side effects of topical anticholinergic drugs are photophobia and blurred vision. Photophobia occurs because paralysis of the iris sphincter prevents the pupil from constricting in response to bright light. Vision is blurred because paralysis of the ciliary muscle prevents focusing for near vision.

104.2.1.1.2.2 Precipitation of Angle-Closure Glaucoma.

By relaxing the iris sphincter, anticholinergic drugs can induce closure of the filtration angle in individuals whose eyes have a narrow angle to begin with. Angle closure occurs as follows: (1) partial dilation of the pupil maximizes contact between the iris and the lens,

thereby impeding egress of aqueous humor from the posterior chamber, and (2) the resultant increase in pressure within the posterior chamber pushes the iris forward, causing blockage of the trabecular meshwork. Caution must be exercised in patients predisposed to angle closure.

104.2.1.1.2.3 Systemic Effects.

Topically applied anticholinergic drugs can be absorbed in amounts sufficient to produce systemic toxicity. Symptoms include dry mouth, blurred vision, photophobia, constipation, fever, tachycardia, and central nervous system effects (confusion, hallucinations, delirium, coma). Death can occur. Muscarinic poisoning can be treated with physostigmine (see [Chapter 14](#)).

104.2.1.2 Phenylephrine (an Adrenergic Agonist)

Adrenergic agonists are mydriatic agents. Pupillary dilation results from activating α_1 -adrenergic receptors on the radial (dilator) muscle of the iris. In contrast to anticholinergic drugs, the adrenergic agonists do not cause cycloplegia. Of the adrenergic agents given to induce mydriasis, *phenylephrine* is the most frequently employed. The adrenergic agonists are discussed at length in [Chapter 17](#). Discussion here is limited to the mydriatic use of phenylephrine.

104.2.1.2.1 Therapeutic and Diagnostic Applications

The mydriatic applications of phenylephrine are much like those of the anticholinergic drugs. Phenylephrine-induced mydriasis is used as an aid to intraocular surgery, measurement of refraction, and ophthalmoscopic examination. In patients with anterior uveitis, phenylephrine is given to dilate the pupil as part of an overall program of treatment.

104.2.1.2.2 Adverse Effects

104.2.1.2.2.1 Effects on the Eye.

Like the anticholinergic drugs, phenylephrine can precipitate angle-closure glaucoma secondary to induction of mydriasis. Caution must be exercised in patients whose filtration angle is naturally narrow. Contraction of the dilator muscle may dislodge pigment granules from degenerating cells of the iris. These granules, which appear as “floaters” in the anterior chamber, are usually cleared from the eye within a day. Phenylephrine may also cause ocular pain, corneal clouding, and brow ache.

104.2.1.2.2.2 Systemic Effects.

Rarely, topical phenylephrine is absorbed in amounts sufficient to produce systemic toxicity. Cardiovascular responses (eg, hypertension, ventricular dysrhythmias, cardiac arrest) are of greatest concern. Other systemic reactions include sweating, blanching, tremor, agitation, and confusion.

^{10...} DRUGS FOR ALLERGIC CONJUNCTIVITIS

104.3.1 Pathophysiology

Allergic conjunctivitis (AC) is defined as inflammation of the conjunctiva in response to an allergen. (The conjunctiva is the delicate membrane that surrounds the eyelids.) AC may be seasonal or perennial (chronic). Primary symptoms are itching, burning, and a thin, watery discharge. In addition, the conjunctivae are usually red and congested.

Symptoms of AC result from a biphasic immune response. Initially, symptoms are caused by release of inflammatory mediators—histamine, prostaglandins, leukotrienes, and kinins—from mast cells. These mediators stimulate mucus production (to cause discharge), activate nerve endings (to cause itching and burning sensations), and promote vasodilation and increase capillary permeability (to cause redness and congestion). These symptoms peak about 20 minutes after allergen exposure and abate 20 minutes later. Following this early response, symptoms typically reappear 6 or more hours later. The late phase is due to recruitment of immune cells—eosinophils, neutrophils, and macrophages—that amplify the inflammatory response.

104.3.2 Drug Therapy

AC can be managed with a variety of topical drugs ([Table 103-5](#)). *Mast-cell stabilizers* (eg, lodoxamide) prevent release of inflammatory mediators. Patients should be informed that benefits take several days to develop, and several weeks to become maximal. In contrast to mast-cell stabilizers, *histamine₁ (H₁)–receptor antagonists* (antihistamines) can provide immediate symptomatic relief. Some drugs (eg, azelastine, olopatadine) have two actions: They prevent mediator release from mast cells and they block H₁ receptors. Ketorolac, a *nonsteroidal anti-inflammatory drug* (NSAID), reduces symptoms by inhibiting cyclooxygenase, an enzyme required for synthesis of prostaglandins. Like the NSAIDs, *glucocorticoids* (eg, loteprednol) inhibit production of prostaglandins; in addition, they inhibit production of leukotrienes and thromboxane. As a result, these drugs are highly effective. Unfortunately, with prolonged use, they can cause serious adverse effects, including cataracts, eye infection, and elevation of IOP. Accordingly, glucocorticoids are generally reserved for short-term therapy in patients who have

1223

1224

not responded adequately to safer drugs. The *ocular decongestants* (eg, naphazoline, phenylephrine) decrease redness and edema by activating α_1 -adrenergic receptors on blood vessels, thereby causing vasoconstriction. Benefits are only symptomatic; these drugs do not interrupt any phase of the immune response. Furthermore, with regular use, rebound congestion is likely.

TABLE 103-5 Topical Drugs for Allergic Conjunctivitis

Class and Generic Name	Trade Name	Concentration	Usual Daily Dosage
Mast-Cell Stabilizers			
Cromolyn sodium	Crolom, Opticrom	4%	1–2 drops every 4–6 hr
Lodoxamide tromethamine	Alomide	0.1%	1–2 drops 4 times daily
Nedocromil sodium	Alocril	2%	1–2 drops twice daily
Pemirolast potassium	Alamast	0.1%	1–2 drops 4 times daily
H₁- Receptor Blockers			
Emedastine difumarate	Emadine	0.05%	1 drop 4 times daily
Mast-Cell Stabilizers/H₁ Blockers			
Azelastine hydrochloride	Optivar	0.05%	1 drop twice daily
Epinastine	Elestat	0.05%	1 drop twice daily
Ketotifen fumarate	Zaditor, Alaway	0.025%	1 drop every 8–12 hr
Olopatadine hydrochloride	Patanol	0.1%	1 drop twice daily
NSAIDs			
Ketorolac tromethamine	Acular	0.5%	1 drop 4 times daily
Glucocorticoids			
Loteprednol etabonate	Alrex	0.2%	1 drop 4 times daily
	Lotemax	0.5%	1–2 drops 4 times daily
Dexamethasone sodium phosphate	various	0.1%	1 drop every 6–8 hours
Prednisolone acetate	various	1%	2 drops every 6–12 hours
Prednisolone sodium phosphate	various	1%	1 drop every 6–8 hours
Decongestants (Vasoconstrictors)			
Naphazoline	Clear Eyes, others	0.012%	1–2 drops up to 4 times daily
Oxymetazoline	Visine L.R., OcuClear	0.025%	1–2 drops 4 times daily
Phenylephrine	Neo-Synephrine, others	0.12%	1–2 drops 4 times daily
Tetrahydrozoline	Visine Moisturizing, others	0.05%	1–2 drops 4 times daily
Decongestant/H₁ Blocker			
Naphazoline/pheniramine	Naphcon-A, others	0.025%/0.3%	1–2 drops 1–4 times a day

NSAIDs = nonsteroidal anti-inflammatory drugs.
--

^{10...} DRUGS FOR AGE-RELATED MACULAR DEGENERATION

^{104.4.1} Pathophysiology of ARMD

Age-related macular degeneration (ARMD) is a painless, progressive disease that blurs central vision, and thereby limits perception of fine detail. Symptoms result from injury to the macula, the central part of the retina that contains the highest density of photoreceptors, and hence provides the high-resolution central vision used for reading, driving, sewing, recognizing faces, and so forth. ARMD is the leading cause of blindness in older Americans. About 15 million have the disease.

ARMD has two forms: dry ARMD (atrophic ARMD) and wet ARMD (neovascular ARMD). Dry ARMD is more common than wet ARMD (85% vs. 15%), but wet ARMD is much more severe and progresses faster. In wet ARMD, macular degeneration is caused by growth of new subretinal blood vessels, which are often fragile and leaky. Fluid leakage lifts the macula from its normal place, which quickly causes permanent injury. In dry ARMD, macular photoreceptors undergo gradual breakdown, leading to gradual blurring of central vision. The disease is characterized by the appearance of *drusen* (yellow deposits under the retina). Drusen develop before any visual impairment occurs. Whether drusen actually cause visual loss is unknown. However, we do know that an increase in the size or number of drusen increases the risk of symptomatic ARMD.

Does ARMD have different stages of severity? Yes. *Dry ARMD* has three stages:

- Early—characterized by a few small- or medium-sized drusen and no change of vision
- Intermediate—characterized by many medium-sized drusen (or one or more large drusen) and minor visual changes (need for increased light for reading, possible blurred spot in the center of the visual field)
- Advanced—characterized by drusen, breakdown of photoreceptors and supporting tissue, and progressive blurring of central vision

What about *wet ARMD*? Everyone with wet ARMD is considered to have *advanced ARMD*. The disease is not divided into stages. All people with wet ARMD have dry ARMD first. Vision loss occurs only in advanced dry ARMD and in wet ARMD.

1224

104.4.2 Management of Dry ARMD

Although we can't prevent vision loss in people with advanced ARMD, we may be able to slow, or perhaps prevent, progression of intermediate disease. In the *Age-Related Eye Disease Study* (AREDS), sponsored by the National Eye Institute, researchers showed that taking high doses of antioxidants and zinc can significantly reduce the risk of developing advanced ARMD. The regimen employed consisted of vitamin C (500 mg), vitamin E (400 IU), beta-carotene (15 mg), and zinc (80 mg), all taken once a day. In addition, participants took 2 mg of copper daily to prevent copper deficiency anemia, which can develop when we consume lots of zinc. The AREDS formulation is recommended for people at high risk of developing advanced ARMD, identified as those with (1) intermediate ARMD in one or both eyes or (2) advanced ARMD (dry or wet) in one eye but not the other. In AREDS, the formulation did not benefit people with early ARMD. The AREDS formulation is available commercially as *Ocuvite PreserVision*.

104.4.3 Management of Wet (Neovascular) ARMD

We have three treatments for neovascular ARMD: laser therapy, photodynamic therapy (PDT), and therapy with angiogenesis inhibitors (ie, drugs that suppress growth of new blood vessels). All three treatments can slow disease progression. In some cases, treatment partially reverses vision loss.

104.4.3.1 Laser Therapy

In laser therapy, high-energy laser light is used to seal leaky blood vessels. Unfortunately, the procedure has several drawbacks. First, laser light can damage nearby retinal tissue, and hence treatment is limited to regions away from the center of the macula. As a result, only a small percentage of leaky vessels can be sealed. Second, since new vessels continue to grow, repeat treatments are usually needed. Third, although the procedure can retard further vision loss, it cannot reverse existing damage. Fourth, even when the procedure is done with care, some loss of vision occurs. This loss is justified by arguing that even greater loss would occur if treatment were withheld.

104.4.3.2 Photodynamic Therapy

Photodynamic therapy employs a photosensitive drug in combination with infrared light. The drug—*verteporfin* [Visudyne]—has a high affinity for neovascular tissue. In the procedure, verteporfin is delivered by IV infusion, and then an infrared laser is shined on the retina for 90 seconds. The light activates the drug, causing it to seal off the vessel. Repeat PDT may be needed because the vessels frequently reopen. Unlike laser therapy, PDT does not injure the

retina. PDT reduces the risk of severe vision loss by 30% to 50%, but only 10% of patients show some improvement in vision. For 5 days after the procedure, patients must protect their skin from sunlight and bright indoor light. Why? Because light-mediated activation of verteporfin could cause severe skin burn.

104.4.3.3 Angiogenesis Inhibitors

104.4.3.3.1 Actions and Benefits.

Three drugs—*pegaptanib* [Macugen], *ranibizumab* [Lucentis], and *bevacizumab* [Avastin]—are used to inhibit growth of new blood vessels in patients with neovascular ARMD. Benefits derive from antagonizing *vascular endothelial growth factor* (VEGF), an endogenous compound that (1) induces angiogenesis, (2) increases vascular permeability, and (3) promotes inflammation—all of which can contribute to neovascular ARMD. Administration is by direct injection into the affected eye every 4 to 6 weeks. Following injection into the vitreous humor, the drugs penetrate to the subretinal blood vessels and then bind with VEGF, thereby preventing VEGF from binding with its receptors on the vascular endothelium. As a result, VEGF is unable to promote vessel growth. The angiogenesis inhibitors are useful in wet ARMD, but not in dry ARMD. For patients with wet ARMD, treatment reduces the risk of losing visual acuity as well as the risk of progressing to blindness. In some cases, treatment partially reverses vision loss.

104.4.3.3.2 Adverse Effects.

The biggest concern is *endophthalmitis*, an inflammation inside the eye caused by bacterial, viral, or fungal infection. Fortunately, the incidence is low (less than 1%). Patients who experience symptoms (eg, redness, light sensitivity, pain) should seek immediate medical attention. More common adverse effects (10% to 40% incidence) include blurred vision, cataracts, conjunctival hemorrhage, corneal edema, eye discharge, increased IOP, ocular discomfort, punctate keratitis, vitreous floaters, and reduced visual acuity. Possible long-term effects—ocular or systemic—are not yet known.

104.4.3.3.3 Pegaptanib, Ranibizumab, and Bevacizumab: Comparisons and Contrasts.

Properties of the three angiogenesis inhibitors used for ARMD are summarized in [Table 103-6](#). As indicated, these agents differ with regard to structure, approved usage, cost, and efficacy.

104.4.3.3.1 Molecular Structure.

Two agents—ranibizumab and bevacizumab—are similar to each other, and both differ from the third agent—pegaptanib. Bevacizumab is an intact monoclonal antibody that binds with VEGF. Ranibizumab is a small fragment of bevacizumab that retains full ability to bind VEGF. In contrast to ranibizumab and bevacizumab, pegaptanib is an oligonucleotide aptamer—that is, a polymer of nucleotides that has been designed to bind with a specific chemical (in this case, VEGF).

TABLE 103-6 Intravitreal Angiogenesis Inhibitors for Neovascular (Wet) ARMD

Generic Name [Trade Name]	Year Approved for ARMD	Type of Molecule	Dosage	Cost per Injection	Comments
Pegaptanib [Macugen]	2004	Oligonucleotide aptamer	0.3 mg every 6 weeks	\$1125	Studies show little or no improvement in visual acuity, and hence use is rare
Ranibizumab [Lucentis]	2006	Antibody fragment	0.5 mg once a month	\$1950	Studies show significant improvement in visual acuity
Bevacizumab [Avastin]	*	Complete antibody	1.25 mg once a month	\$30	Studies show significant improvement in visual acuity
ARMD = age-related macular degeneration.					

* Bevacizumab is approved for metastatic colorectal cancer, but not for ARMD.

104.4.3.3.2 Approved Usage and Cost.

Both pegaptanib and ranibizumab are approved for neovascular ARMD. In contrast, bevacizumab is approved for colorectal cancer, but not for ARMD. Nonetheless, bevacizumab is being used off-label for ARMD, in part because it is much less expensive than the other two drugs (see [Table 103-6](#)).

104.4.3.3.3 Efficacy.

All three drugs greatly reduce the risk of further visual impairment and progression to blindness. In addition, studies have shown that two agents—ranibizumab and bevacizumab

—can *improve* visual acuity that has been impaired. As for pegaptanib, studies to date show little evidence of visual improvement. As a result, pegaptanib is used rarely.

^{10...} ADDITIONAL OPHTHALMIC DRUGS

^{104.5.1} Demulcents (Artificial Tears)

Ophthalmic demulcents are isotonic solutions employed as substitutes for natural tears. Most preparations contain *polyvinyl alcohol*, *cellulose esters*, or both. Artificial tears are indicated for relieving dry-eye syndromes and discomfort and dryness caused by irritants, wind, and sun. In addition, demulcents may be used to lubricate artificial eyes. Artificial tears are devoid of adverse effects, and hence may be administered as often and as long as desired.

^{104.5.2} Ocular Decongestants

Ocular decongestants are weak solutions of adrenergic agonists applied topically to constrict dilated conjunctival blood vessels. These preparations are used to reduce redness of the eye caused by minor irritation. The adrenergic agents employed as decongestants are *phenylephrine*, *naphazoline*, *oxymetazoline*, and *tetrahydrozoline*. When applied to the eye in the low concentrations found in decongestant products, adrenergic agonists rarely cause adverse effects. Local reactions (stinging, burning, reactive hyperemia) may occur with overuse. The adrenergic agonists are discussed at length in [Chapter 17](#).

^{104.5.3} Glucocorticoids

Glucocorticoids (anti-inflammatory corticosteroids) are used for inflammatory disorders of the eye (eg, uveitis, iritis, conjunctivitis). Administration may be topical or by local injection. Short-term therapy is generally devoid of adverse effects. In contrast, prolonged therapy may cause cataracts, reduced visual acuity, and glaucoma. In addition, there is an increased risk of infection secondary to corticosteroid-induced suppression of host defenses. The glucocorticoids are discussed at length in [Chapter 71](#).

^{104.5.4} Dyes

Fluorescein is a water-soluble dye that produces an intense green color. This agent is applied to the surface of the eye to detect lesions of the corneal epithelium; intact areas of the cornea remain uncolored while abrasions and other defects turn bright green. Intravenous fluorescein is used to facilitate visualization of retinal blood vessels; IV fluorescein has been employed to help evaluate diabetic retinopathy and other abnormalities of the retinal vasculature. Fluorescein can also be used topically and intravenously to assess flow of aqueous humor. Adverse effects from

systemic administration include nausea, vomiting, paresthesias, and pruritus. Severe reactions (anaphylaxis, pulmonary edema, cardiac arrest) are rare.

Rose bengal is applied topically to visualize abrasions of the corneal and conjunctival epithelium. Injured tissue appears rose colored when viewed with a slit lamp. The dye is employed for diagnosis of superficial injury to corneal and conjunctival tissue.

104.5.5 Antiviral Agents

Four drugs—*trifluridine*, *vidarabine*, *ganciclovir*, and *idoxuridine*—are used topically to treat viral infections of the eye. Their pharmacology and specific applications are discussed in [Chapter 92](#).

104.5.5.1 KEY POINTS

- The glaucomas are a group of diseases characterized by visual field loss secondary to optic nerve damage.
- In open-angle glaucoma, optic nerve injury develops gradually over years. The cause of nerve damage is unknown.
- In angle-closure glaucoma, there is blockage of aqueous humor outflow, which causes an abrupt rise in IOP. In the absence of treatment, irreversible damage to the optic nerve occurs in 1 or 2 days.
- Drug therapy of open-angle glaucoma is directed at reducing elevated IOP, the major risk factor for this disease.
- Angle-closure glaucoma is treated with drugs to rapidly reduce IOP and then with corrective surgery to allow aqueous humor outflow.
- Drugs reduce IOP by either facilitating aqueous humor outflow or reducing aqueous humor production.
- Three drug families—beta blockers, alpha₂-adrenergic agonists, and prostaglandins—are considered first-line agents for topical therapy of open-angle glaucoma.
- Timolol and other topical beta blockers lower IOP by decreasing aqueous humor production.
- Topical beta blockers can be absorbed in amounts sufficient to cause bronchospasm, bradycardia, and AV heart block.

- Brimonidine, an α_2 agonist, lowers IOP by decreasing aqueous humor production, and possibly by increasing aqueous humor outflow.
- Latanoprost and other prostaglandin analogs lower IOP by facilitating aqueous humor outflow.
- Prostaglandins can increase brown pigmentation of the iris, and can intensify pigmentation of the skin around the eye.
- Cycloplegics are drugs that paralyze the ciliary muscle.
- Mydriatics are drugs that dilate the pupil.
- Atropine and other anticholinergic drugs cause cycloplegia by blocking muscarinic receptors on the ciliary muscle, and cause mydriasis by blocking muscarinic receptors on the iris sphincter.
- By paralyzing the ciliary muscle, anticholinergic drugs prevent the eye from focusing for near vision.
- By paralyzing the iris sphincter, anticholinergic drugs prevent the pupil from constricting in response to bright light; photophobia results.
- Phenylephrine, an adrenergic agonist, causes mydriasis by stimulating α -adrenergic receptors on the radial (dilator) muscle of the iris.
- Age-related macular degeneration (ARMD) is a progressive disease that blurs central vision, and thereby limits perception of fine detail.
- ARMD has two forms: dry ARMD (atrophic ARMD) and wet ARMD (neovascular ARMD). Neovascular ARMD is much less common, but much more severe.
- In people with intermediate dry ARMD, prophylactic treatment with high-dose antioxidants and zinc may prevent the disease from progressing to the advanced stage.
- Wet ARMD can be treated with laser therapy, photodynamic therapy, and angiogenesis inhibitors (drugs that block retinal angiogenesis by neutralizing vascular endothelial growth factor).

¹⁰⁵CHAPTER 104 Drugs for the Skin

Our objective in this chapter is to discuss some of the more frequently encountered dermatologic drugs. Most are employed topically; some are given systemically. Before discussing the dermatologic drugs, we review the anatomy of the skin.

^{10...}ANATOMY OF THE SKIN

The skin is composed of three distinct layers: the epidermis, the dermis, and a layer of subcutaneous fat. These layers and other features of the skin are depicted in [Figure 104-1](#).

^{105.1.1}Epidermis.

The epidermis is the outermost layer of the skin and is composed almost entirely of closely packed cells. As indicated in [Figure 104-1B](#), the epidermis itself consists of several layers. The deepest, known as the *basal layer* or *stratum germinativum*, contains the only epidermal cells that are mitotically active. All cells of the epidermis arise from this layer. Production of new cells within the basal layer pushes older cells outward. During their migration, these cells become smaller and flatter. As epidermal cells near the surface of the skin, they die and their cytoplasm is converted to *keratin*, a hard, proteinaceous material. Because of its high content of keratin, the outer layer of the epidermis has a rough, horny texture. Because of its texture, this layer is referred to as the *cornified layer* or *stratum corneum*. By a process that is not fully understood, the surface of the stratum corneum undergoes continuous exfoliation (shedding). This shedding completes the growth cycle of the epidermis.

In addition to germinal cells, the basal layer of the epidermis contains *melanocytes*. These cells, which are few in number, produce *melanin*, the pigment that determines skin color. Following its synthesis within melanocytes, melanin is transferred to other cells of the epidermis. Melanin protects the skin against ultraviolet radiation, which is the principal stimulus for melanin production.

^{105.1.2}Dermis.

The dermis underlies the epidermis and is composed largely of connective tissue, primarily collagen. A major function of the dermis is to provide support and nourishment for the epidermis. Structures found in the dermis include blood vessels, nerves, and muscle. The dermis also contains sweat glands, sebaceous glands, and hair follicles. Sebaceous glands secrete an oily composite known as sebum. Almost all sebaceous glands are associated with hair follicles (see [Fig. 104-1A](#)).

^{105.1.3} Subcutaneous Tissue.

Subcutaneous tissue consists largely of fat. This fatty layer provides protection and insulation. In addition, the stored fat constitutes a reserve source of calories.

^{10...} TOPICAL GLUCOCORTICOIDS

The basic pharmacology of the glucocorticoids (anti-inflammatory corticosteroids) is discussed in [Chapter 71](#). Consideration here is limited to their use for disorders of the skin.

^{105.2.1} Actions and Uses.

Topical glucocorticoids are employed to relieve inflammation and itching associated with a variety of dermatologic disorders (eg, insect bites, minor burns, seborrheic dermatitis, psoriasis, eczema, pemphigus). The mechanisms by which glucocorticoids suppress inflammation and other symptoms are discussed in [Chapter 71](#).

The vehicle in which a glucocorticoid is dispersed (eg, cream, ointment, gel) can enhance the therapeutic response by helping the glucocorticoid penetrate to its site of action. The vehicle may provide additional benefits by acting as a drying agent or an emollient.

1227

1228

Figure 104-1 Anatomy of the skin. **A**, Major structures of the skin. **B**, Growth layers of the epidermis.

105.2.2 Relative Potency.

Glucocorticoid preparations vary widely in potency. As indicated in [Table 104-1](#), steroid preparations can be assigned to four groups, which range from low potency to super-high potency. Preparations within each group are about equally potent.

It is important to note that the intensity of the response to topical glucocorticoids depends not only on the concentration and inherent activity of the glucocorticoid, but also on the vehicle employed and the method of application. Occlusive dressings can enhance percutaneous absorption by as much as 10-fold, thereby greatly increasing pharmacologic effects.

105.2.3 Absorption.

Topical glucocorticoids can be absorbed into the systemic circulation. The extent of absorption is proportional to the duration of use and the surface area covered. Absorption is higher from regions where the skin is especially permeable (scalp, axilla, face, eyelids, neck, perineum, genitalia) and lower from regions where penetrability is poor (back, palms, soles). Absorption through intact skin is less than through inflamed skin. As noted, absorption is influenced by the vehicle, and can be greatly increased by use of an occlusive dressing.

105.2.4 Adverse Effects.

Adverse effects may be local or systemic. Factors that increase the risk of adverse effects include use of high-potency glucocorticoids, use of occlusive dressings, prolonged therapy, and application over a large surface area.

105.2.4.1 Local Reactions.

Glucocorticoids increase the risk of local infection, and may also produce irritation. With prolonged use, glucocorticoids can cause atrophy of the dermis and epidermis, resulting in thinning of the skin, striae (stretch marks), purpura (red spots caused by local hemorrhage), and telangiectasia (red, wart-like lesions caused by capillary dilation). Long-term therapy may induce acne and hypertrichosis (excessive growth of hair, especially on the face).

105.2.4.2 Systemic Toxicity.

Topical glucocorticoids can be absorbed in amounts sufficient to produce systemic toxicity. Principal concerns are growth retardation (in children) and adrenal suppression (in all age groups). Systemic toxicity is more likely under extreme conditions of use (prolonged therapy in which extensive surfaces are treated with large doses of high-potency agents in conjunction

with occlusive dressings). When these conditions are present, the hypothalamic-pituitary-adrenal axis should be monitored. Systemic toxicity of the glucocorticoids is discussed at length in [Chapter 71](#).

105.2.5 Administration.

Topical glucocorticoids should be applied in a thin film and gently rubbed into the skin. Patients should be advised not to use occlusive dressings (bandages, plastic wraps) unless the prescriber tells them to. Tight-fitting diapers and plastic pants can act as occlusive dressings and should not be worn when glucocorticoids are applied to the diaper region of infants.

10... KERATOLYTIC AGENTS

Keratolytic agents are drugs that promote shedding of the horny layer of the skin. Effects range from peeling to extensive desquamation of the stratum corneum. Two keratolytic compounds—*salicylic acid* and *sulfur*—are considered below. A third agent—*benzoyl peroxide*—is discussed later under *Topical Drugs for Acne*.

105.3.1 Salicylic Acid.

Salicylic acid promotes desquamation by dissolving the intracellular cement that binds scales to the stratum corneum. Keratolytic effects are achieved with concentrations between 3% and 6%. At concentrations above 6%, tissue injury is likely. Low (3% to 6%) concentrations are used to treat dandruff, seborrheic dermatitis, acne, and psoriasis. Higher concentrations (up to 40%) are used to remove warts and corns.

Salicylic acid is readily absorbed through the skin, and systemic toxicity (salicylism) can result. Symptoms include tinnitus, hyperpnea, and psychologic disturbances. Systemic effects can be minimized by avoiding prolonged use of high concentrations over large areas.

105.3.2 Sulfur.

Sulfur promotes peeling and drying. The compound has been used to treat acne, dandruff, psoriasis, and seborrheic dermatitis. Sulfur is available in lotions, gels, and shampoos. Concentrations range from 2% to 10%.

1228

TABLE 104-1 Relative Potency of Topical Glucocorticoids

Potency Class and Drug	Formulation	Concentration
Super-High Potency		
Betamethasone dipropionate [Diprolene]	Cream, ointment, lotion	0.05%
Clobetasol propionate [Temovate]	Cream, ointment, gel, spray	0.05%
Diflorasone diacetate [Psorcon, Maxiflor, Florone]	Ointment	0.05%
Fluocinonide [Vanos]	Cream	0.1%
Halobetasol propionate [Ultravate]	Cream, ointment	0.05%
High Potency		
Amcinonide	Cream, ointment, lotion	0.1%
Betamethasone dipropionate [Diprosone]	Cream, ointment	0.05%
Desoximetasone [Topicort]	Cream, ointment	0.25%
Diflorasone diacetate [Florone, Maxiflor]	Cream, ointment	0.05%
Flucinolone acetonide	Cream	0.2%
Fluocinonide [Fluonex, Lidex]	Cream, ointment, gel	0.05%
Halcinonide [Halog]	Cream, ointment	0.1%
Triamcinolone acetonide	Ointment	0.1%
Medium Potency		
Betamethasone benzoate	Lotion	0.025%
Betamethasone dipropionate [Diprosone, others]	Lotion	0.05%
Betamethasone valerate [Valisone]	Cream, ointment, lotion	0.1%
Clocortolone pivalate [Cloderm]	Cream	0.1%
Desoximetasone [Topicort]	Cream	0.05%
Fluocinolone acetonide	Cream, ointment	0.025%
Flurandrenolide [Cordran]	Cream, ointment, lotion	0.05%
Fluticasone propionate [Cutivate]	Ointment	0.005%
	Cream	0.05%
Halcinonide [Halog]	Cream	0.025%
Hydrocortisone valerate [Westcort]	Cream, ointment	0.2%
Mometasone furoate [Elocon]	Cream, ointment, lotion	0.1%
Triamcinolone acetonide [Kenalog]	Cream, ointment, lotion	0.1%
Low Potency		

Pharmacology for Nursing Care, 7th Edition

Alclometasone dipropionate [Aclovate]	Cream, ointment	0.05%
Desonide [DesOwen]	Aerosol	0.04%
Dexamethasone [Decaspray]	Aerosol	0.04%
Dexamethasone sodium phosphate [Decadron phosphate]	Cream	0.1%
Fluocinolone acetonide	Cream, solution	0.01%
Hydrocortisone [Cortizone-10, Hycort]	Cream, ointment, lotion	1%

10... ACNE

Acne is the most common dermatologic disease. About 85% of teenagers develop acne, which often persists into adulthood. Acne accounts for more visits to dermatologists than any other disorder. In the United States, the direct costs of acne exceed \$1 billion a year, including about \$100 million spent on acne products sold over the counter.

105.4.1 Pathophysiology

Acne is a chronic skin disorder that usually begins during puberty. The disease is more common and more severe in males. Lesions usually develop on the face, neck, chest, shoulders, and back. In mild acne, *open comedones* (blackheads) are the most common lesion. A comedo forms when sebum combines with keratin to create a plug within a pore (oxidation of the sebum causes the exposed surface of the plug to turn black). *Closed comedones* (whiteheads) develop when pores become stuffed with sebum and scales below the skin surface. In its most severe form, acne is characterized by abscesses and inflammatory cysts. As a rule, acne begins to resolve after puberty and clears entirely during the early 20s. However, with some people, the disease continues for decades.

Onset of acne is initiated by increased production of androgens during adolescence. Under the influence of androgens, sebum production and turnover of follicular epithelial cells are increased, leading to plugging of pores. Symptoms are intensified by the activity of *Propionibacterium acnes*, a microbe that converts sebum into irritant fatty acids. This bacterium also releases chemotactic factors that promote inflammation. Oily skin and a genetic predisposition are additional contributing factors.

1229

105.4.2 Overview of Treatment

1230

Because acne is a chronic disease, treatment is prolonged. Fortunately, almost all patients respond well. Effective treatment will prevent scarring and limit the duration of symptomatic disease, and will thereby minimize the psychologic effects of acne.

105.4.2.1 Nondrug Therapy

Nondrug measures can help minimize lesions, especially in patients with milder acne. Surface oiliness should be reduced by gentle cleansing 2 or 3 times a day. Care should be taken to avoid irritation from vigorous scrubbing or use of abrasives. Oil-based moisturizing products should be avoided. Additional nondrug measures (eg, comedo extraction, dermabrasion) may be indicated for some individuals. Dietary measures don't help.

105.4.2.2 Drug Therapy

Drugs for acne fall into two major groups: topical drugs and oral drugs ([Table 104-2](#)). The topical drugs have two principal subgroups: antimicrobial agents and retinoids. Likewise, the oral drugs have two principal subgroups: antibiotics and retinoids.

Drug selection is based on symptom severity. For patients with relatively mild symptoms, topical therapy can suffice. When symptoms are more severe, oral therapy is required. *Mild* acne can be managed with topical antimicrobials and topical retinoids. *Moderate* acne can be treated with oral antibiotics (eg, doxycycline, minocycline) and comedolytics (retinoids and azelaic acid). In addition, hormonal agents—combination oral contraceptives (OCs) and spironolactone—can be used in young women. The principal agent for *severe* acne is isotretinoin.

TABLE 104-2 Drugs for Acne

Topical Drugs
Antibiotics
Benzoyl peroxide (generic only)
Clindamycin [Cleocin, others]
Erythromycin [Eryderm, others]
Dapsone [Aczone]
Retinoids
Tretinoin [Retin-A, Avita]
Adapalene [Differin]
Tazarotene [Tazorac]
Others
Azelaic acid [Azelex]
Oral Drugs
Antibiotics
Doxycycline [Vibramycin, others]
Minocycline [Dynacin, Minocin, Solodyn]
Tetracycline [Sumycin, others]
Erythromycin [Ery-Tab, others]
Retinoids
Isotretinoin [Accutane]
Hormonal Agents
Combination oral contraceptives
Spirolonolactone [Aldactone]

105.4.3 Topical Drugs for Acne

105.4.3.1 Antibiotics

105.4.3.1.1 Benzoyl Peroxide.

Benzoyl peroxide is a first-line drug for mild to moderate acne. Improvement can be seen within days of starting treatment. Benefits derive primarily from suppressing growth of *P. acnes*. The presumed mechanism is release of active oxygen. In addition to suppressing *P. acnes*, benzoyl peroxide can reduce inflammation and promote keratolysis (peeling of the horny layer of the epidermis). In one study, topical benzoyl peroxide was at least as effective as *oral* minocycline.

Unlike other topical antimicrobials, benzoyl peroxide does not promote emergence of resistant *P. acnes*. In fact, the drug is often combined with clindamycin or erythromycin to protect against resistance, which can occur when those antibiotics are used alone.

Benzoyl peroxide may produce drying and peeling of the skin. If signs of severe local irritation occur (eg, burning, blistering, scaling, swelling), the frequency of application should be reduced.

Some formulations contain sulfites, which can cause potentially serious allergic reactions. The incidence is highest in patients with asthma. Otherwise, the incidence is low.

Benzoyl peroxide is available in a variety of formulations (eg, lotions, creams, gels). Concentrations range from 2.5% to 10%. For initial therapy, once-daily application is recommended. Over time, the frequency of administration can be increased (to a maximum of 3 times a day) as tolerance permits. Patients should be advised to keep the drug away from the eyes, mouth, and mucous membranes, as well as inflamed or denuded skin.

105.4.3.1.2 Clindamycin and Erythromycin.

Like benzoyl peroxide, topical clindamycin [Cleocin, others] and erythromycin [Eryderm, others] suppress growth of *P. acnes*. In addition, these two drugs can decrease inflammation. Monotherapy with either drug quickly leads to resistance. To protect against emergence of resistance, these drugs can be combined with benzoyl peroxide. Two fixed-dose combinations are available: clindamycin/benzoyl peroxide, sold as *BenzaClin*; and erythromycin/benzoyl peroxide, sold as *Benzamycin*.

105.4.3.1.3 Dapsone.

Dapsone [Aczone], approved for topical therapy of acne in 2008, has been used for oral therapy of leprosy for decades (see [Chapter 89](#)). In patients with acne, the drug yields a modest decrease in inflammation and number of lesions. The mechanism underlying these benefits has not been established. Comparative trials with other topical agents have not been conducted. Dapsone is available as a 5% gel in 30-gm tubes for twice-daily application. The application site should be washed and dried before applying the drug, and the hands should be washed afterward. The most common side effects—oiliness (19%), peeling (19%), dryness (16%), and erythema (13%)—are caused primarily by the gel vehicle, and not by dapsone. Unlike oral dapsone, topical dapsone does not pose a risk of hemolytic anemia or peripheral neuropathy. Combining dapsone with benzoyl peroxide can turn the skin yellow or orange, and hence should be avoided. Until more is known, dapsone should be reserved for patients who can't tolerate traditional topical treatments.

105.4.3.2 Retinoids

The topical retinoids—derivatives of vitamin A (retinol)—are a cornerstone of acne therapy. These drugs can unplug existing comedones and prevent development of new ones. In addition, they can reduce inflammation and improve penetration of other topical agents. The retinoids may be used alone or in combination with other drugs, including topical and oral antimicrobials.

105.4.3.2.1 Tretinoin.

Tretinoin [Retin-A, Retin-A Micro, Avita, Renova], a derivative of vitamin A, is used for
acne and to remove fine wrinkles. Formulations for acne are marketed as Retin-A and Avita.
The formulation for wrinkles, which is nearly identical to one of the formulations for acne, is
marketed as Renova. Tretinoin should not be confused with isotretinoin, a powerful *oral*
antiacne medicine (see below).

105.4.3.2.1.1 Use for Acne.

Tretinoin is approved for topical treatment of mild to moderate acne. Benefits derive from normalizing hyperproliferation of epithelial cells within hair follicles. By doing so, retinoids can unplug existing comedones and suppress formation of new plugs. Tretinoin also causes thinning of the stratum corneum, and can thereby facilitate penetration of other drugs. Therapeutic effects can be enhanced by combining tretinoin with benzoyl peroxide and oral antibiotics.

105.4.3.2.1.2 Use for Fine Wrinkles.

Tretinoin is approved for reducing fine wrinkles, tactile roughness, and mottled hyperpigmentation (liver spots, age spots) in facial skin. Benefits may derive from suppressing genes that code for specific proteases that break down collagen and elastin. In clinical trials, responses to tretinoin were modest. In fact, many patients achieved equivalent effects with a program of comprehensive skin care and sun protection. It is important to appreciate that tretinoin does *not* repair deep, coarse wrinkles and other damage caused by chronic sun exposure. Furthermore, the drug does not eliminate wrinkles, repair sun-damaged skin, reverse photoaging, or restore the microscopic structure of skin to a more youthful pattern. Lastly, benefits in patients over the age of 50 have not been established.

105.4.3.2.1.3 Adverse Effects.

Tretinoin can cause *localized* reactions, but absorption is insufficient to cause systemic toxicity. In patients with sensitive skin, tretinoin may induce blistering, peeling, crusting, burning, and edema. These effects can be intensified by concurrent use of abrasive soaps and keratolytic agents (eg, sulfur, resorcinol, benzoyl peroxide, salicylic acid). Accordingly, these preparations should be discontinued prior to tretinoin therapy. Skin reactions with two formulations—Avita and Retin-A Micro—may be less intense than those caused by Retin-A, an older formulation.

Tretinoin increases susceptibility to sunburn. Patients should be warned to apply a sunscreen (sun protection factor [SPF] of 15 or greater) and wear protective clothing. Patients with existing sunburn should not apply the drug.

105.4.3.2.1.4 Preparations, Dosage, and Administration.

For treatment of *acne*, tretinoin is available under three trade names: Retin-A, Retin-A Micro, and Avita. Products marketed as *Retin-A* are available in three formulations: cream (0.025%, 0.05%, and 0.1%), gel (0.01% and 0.025%), and liquid (0.05%). *Retin-A Micro* is supplied as a 0.1% gel, and *Avita* as a 0.025% cream. All products are administered topically, usually once a day at bedtime. Before application, the skin should be washed, toweled dry, and allowed to dry fully for 15 to 30 minutes. Tretinoin should not be applied to open wounds or to areas of sunburn or windburn. Contact with the eyes, nose, and mouth should be avoided.

For *fine wrinkles of the face*, tretinoin is available in a 0.05% cream, sold as *Renova*. Application is done once daily at bedtime. Cosmetics should be washed off before use. Up to 6 months of treatment may be needed to see a response, and treatment must continue to maintain the response.

105.4.3.2.2 Adapalene.

Adapalene [Differin] is a topical antiacne drug similar to tretinoin. Through actions in the cell nucleus, adapalene modulates inflammation, epithelial keratinization, and differentiation of follicular cells. As a result, the drug reduces formation of comedones and inflammatory lesions. Benefits take 8 to 12 weeks to develop. During the early weeks, adapalene may appear to exacerbate acne by affecting previously invisible lesions. In clinical trials, 0.1% adapalene gel was as effective as 0.025% tretinoin gel in reducing the total number of comedones, and was more effective than tretinoin in reducing the total number of acne lesions and inflammatory lesions.

Adverse effects are limited to sites of application. The drug is not absorbed, and hence systemic effects are absent. Common side effects include burning (10% to 40%), pruritus or burning immediately after application (20%), erythema, dryness, and scaling. These are most likely during the first 2 to 4 weeks of treatment and tend to subside as treatment continues.

Adapalene increases the risk of developing sunburn and can intensify existing sunburn. Accordingly, all patients should apply a sunscreen and wear protective clothing. In addition, adapalene should not be used until existing sunburn has resolved.

Adapalene is available in three 0.1% formulations—gel, cream, and solution—for once-daily application in the evening. Contact with the eyes, lips, and mucous membranes should be avoided.

105.4.3.2.3 Tazarotene.

Tazarotene [Avage, Tazorac] is indicated for topical therapy of acne, wrinkles, and psoriasis. Like tretinoin and adapalene, tazarotene is a derivative of vitamin A. For treatment of acne, tazarotene is available in a 0.1% gel and 0.1% cream. The gel or cream is applied to affected areas of the face each evening. The face should be cleaned and dried before application. The most common side effects—itching, burning, and dry skin—occur more often with tazarotene than with tretinoin or adapalene. Like other retinoids, tazarotene sensitizes the skin to ultraviolet light, and hence patients should be advised to use a sunscreen and wear

protective clothing. The basic pharmacology of tazarotene is discussed below under *Topical Drugs for Psoriasis*.

105.4.3.3 Azelaic Acid

Azelaic acid [Azelex] is a topical drug for mild to moderate acne. It appears to work by suppressing growth of *P. acnes* and by decreasing proliferation of keratinocytes, thereby decreasing the thickness of the stratum corneum. In clinical trials, topical azelaic acid (20% cream) was as effective as 5% benzoyl peroxide, 0.05% tretinoin, or 2% erythromycin. For severe acne, azelaic acid was much less effective than oral isotretinoin. Adverse effects—which are uncommon and less intense than with tretinoin or benzoyl peroxide—include pruritus, burning, stinging, tingling, and erythema. Azelaic acid may decrease pigmentation in patients with dark complexions. Hence, these people should be monitored for hypopigmentation. Azelaic acid is applied twice daily by gently massaging a thin film into the affected area. Contact with the eyes, nose, and mouth should be avoided. Before application, the skin should be washed and patted dry.

105.4.4 Oral Drugs for Acne

105.4.4.1 Antibiotics

Oral antibiotics are used for moderate to severe acne. These drugs suppress growth of *P. acnes* and directly suppress inflammation. As a rule, oral antibiotics are combined with a topical retinoid.

At this time, doxycycline [Vibramycin, others] and minocycline [Minocin, Dynacin, Solodyn] are considered agents of choice. Tetracycline [Sumycin, others] and erythromycin [Ery-Tab, others] are alternatives, but resistance to these drugs is common. With all antibiotics, benefits develop slowly, taking 3 to 6 months to reach their maximum. After symptoms have been controlled with an oral antibiotic, patients should switch to a topical antibiotic for long-term maintenance.

105.4.4.2 Isotretinoin

105.4.4.2.1 Actions and Use.

Isotretinoin [Accutane, Amnesteem, Claravis, Sortet], a derivative of vitamin A, is used to treat *severe nodulocystic acne vulgaris*, a condition for which this drug is highly effective. For most patients, a single course of therapy can produce complete and prolonged remission. Because isotretinoin can cause serious side effects, use is restricted to patients with severe,

disfiguring acne that has not responded to more conventional agents, including oral antibiotics. Accutane is highly teratogenic, and hence must not be used during pregnancy.

Isotretinoin has several actions that may contribute to antiacne effects. The drug decreases sebum production, sebaceous gland size, inflammation, and keratinization. In addition, by decreasing availability of sebum, a nutrient for *P. acnes*, isotretinoin lowers the skin population of this microbe.

1231

105.4.4.2.2 Pharmacokinetics.

1232

Absorption from the GI tract is rapid but incomplete. Food greatly increases absorption. In the blood, isotretinoin is nearly 100% bound to albumin. The drug undergoes metabolism in the liver and possibly in cells of the intestinal wall. Excretion is by renal and biliary processes. The drug's half-life is 10 to 20 hours.

105.4.4.2.3 Adverse Effects.

105.4.4.2.3.1 Common Effects.

The most common reactions are nosebleeds (80%), inflammation of the lips (90%), inflammation of the eyes (40%), and dryness or itching of the skin, nose, and mouth (80%). About 15% of patients experience pain, tenderness, or stiffness in muscles, bones, and joints. Among pediatric patients, nearly 30% experience back pain. Less common reactions include skin rash, headache, hair loss, and peeling of skin from the palms and soles. Reduction in night vision has occurred, sometimes with sudden onset. The skin may become sensitized to ultraviolet light; patients should be advised to wear protective clothing or a sunscreen if responses to sunlight become exaggerated. Rarely, isotretinoin causes cataracts, optic neuritis, papilledema (edema of the optic disk), and pseudotumor cerebri (benign elevation of intracranial pressure).

Triglyceride levels may become elevated. Blood triglyceride content should be measured prior to treatment and periodically thereafter until effects on triglycerides have been evaluated. Alcohol can potentiate hypertriglyceridemia and should be avoided.

Although the above adverse effects occur frequently, they usually reverse upon discontinuing the drug.

105.4.4.2.3.2 Rare Effect: Depression.

Isotretinoin may pose a small risk of depression and suicide, although proof of a causal relationship is lacking. With some patients, depression developed while taking isotretinoin,

resolved when the drug was discontinued, and then recurred when treatment was resumed. Between 1982 and January 2005, 190 suicides were reported. However, there is no definitive proof that isotretinoin was the cause, and no mechanism for inducing depression has been established. Nonetheless, because the potential consequences of depression are severe, steps should be taken to minimize risk. Accordingly, clinicians should ask patients to report signs of depression (eg, depressed mood, loss of interest or pleasure) or thoughts of suicide. If these occur, isotretinoin should be withdrawn. Psychiatric evaluation should be obtained as indicated.

105.4.4.2.4 Drug Interactions.

Adverse effects of isotretinoin can be increased by *tetracyclines* and *vitamin A*. Tetracyclines increase the risk of pseudotumor cerebri and papilledema. Vitamin A, a close relative of isotretinoin, can produce generalized intensification of isotretinoin toxicity. Because of the potential for increased toxicity, tetracyclines and vitamin A supplements should be discontinued prior to isotretinoin therapy.

105.4.4.2.5 Contraindication: Pregnancy.

Isotretinoin is teratogenic and must not be used during pregnancy. The drug is classified in Food and Drug Administration (FDA) Pregnancy Risk Category X: The risks of use during pregnancy clearly outweigh any possible benefits. Major fetal abnormalities that have occurred include hydrocephalus, microcephaly, facial malformation, cleft palate, cardiovascular defects, and abnormal formation of the outer ear.

105.4.4.2.6 iPLEDGE Program.

iPLEDGE is the name of a very strict risk management program designed to ensure that no woman starting isotretinoin *is* pregnant and that no woman taking isotretinoin *becomes* pregnant. The iPLEDGE program, which went into effect December 31, 2005, replaces S.M.A.R.T. (System to Manage Accutane-Related Teratogenicity) and all other programs designed to guard against use of isotretinoin during pregnancy. The principal difference between iPLEDGE and S.M.A.R.T. is that, under iPLEDGE, all transactions involving isotretinoin must be processed through a *central automated system*, which tracks and verifies critical elements that control access to the drug. The program has rules that apply to the prescriber, patient, pharmacist, and wholesaler. Details regarding iPLEDGE are available online at www.ipledgeprogram.com.

105.4.4.2.6.1 Requirements for Female Patients.

Each patient must receive oral and written warnings about the high risk of fetal harm if isotretinoin is taken during pregnancy.

Pregnancy must be ruled out before the initial prescription, and again before each monthly refill. Prior to the initial prescription, the patient must undergo *two* pregnancy tests, both of which must be negative. For the monthly refills, only one negative test result is required.

Each patient must use *two* effective forms of birth control, even if one of them is tubal ligation or vasectomy of the male partner. In addition, the patient must review educational material, provided through iPLEDGE, on contraceptive methods, possible reasons for contraceptive failure, and the importance of using effective contraception while taking a teratogenic drug. Birth control measures must be implemented at least 1 month before starting isotretinoin, and must continue at least 1 month after stopping. Birth control is not required following hysterectomy or for women who commit to total abstinence from sexual intercourse.

Each patient must sign a Patient Information/Informed Consent document, designed to reinforce the benefits and risks of isotretinoin use.

Each patient must be registered with iPLEDGE by her prescriber, and must contact iPLEDGE (through the Internet or by phone) before starting treatment, once a month during treatment, and, finally, 1 month after stopping treatment. At each contact, the patient must answer questions on program requirements and must indicate her two chosen methods of birth control.

105.4.4.2.6.2 Requirements for Prescribers.

Prescribers must register with iPLEDGE and must agree to follow key points of the iPLEDGE program, as described in the *iPLEDGE Program Guide to Best Practices for Isotretinoin*. Also, the prescriber must register each patient with iPLEDGE, enter the results of each monthly pregnancy test, and indicate what methods of contraception the patient is using. The initial prescription for isotretinoin and each monthly refill must be entered into the iPLEDGE system.

105.4.4.2.6.3 Requirements for Pharmacists.

To dispense isotretinoin, pharmacists must be registered with iPLEDGE, and must obtain the drug through an iPLEDGE-registered wholesaler. Every time a prescription for isotretinoin is filled, the pharmacist must

- Contact iPLEDGE for authorization
- Confirm with iPLEDGE that the prescription is no more than 7 days old
- Dispense no more than a 30-day supply at a time
- Write the risk management authorization (RMA) number on the prescription

1232

105.4.4.2.7 Preparations, Dosage, and Administration.

1233

Isotretinoin is available in standard capsules (10, 20, and 40 mg) sold as Accutane, Amnesteem, and Claravis, and in soft-gel capsules (10, 20, 30, and 40 mg) sold as Sortet. The usual course of treatment is 0.5 to 1 mg/kg/day (taken in two divided doses with food) for 15 to 20 weeks. If needed, a second course may be given, but no sooner than 2 months after completing the first course.

105.4.4.3 Hormonal Agents

Hormonal therapies can be used for acne in young women. Combination oral contraceptives and spironolactone are the main agents employed. In both cases, benefits derive from decreasing androgen activity, leading to decreased production of sebum.

105.4.4.3.1 Oral Contraceptives.

Three combination oral contraceptives (OCs)—Estrostep, Ortho Tri-Cyclen, and Yaz—are approved for managing acne in women. Treatment is limited to females at least 15 years old who want contraception, have reached menarche, and have not responded to topical drugs. Acne may take 6 or more months to improve. Benefits are due primarily to the *estrogen* in combination OCs—not the progestin. Two mechanisms are involved: suppression of ovarian androgen production, and increased production of *sex hormone-binding globulin*, a protein that binds androgens and thereby renders them inactive. By decreasing androgen availability, estrogens decrease production of sebum. Although only three OCs are approved for acne, all estrogen-containing OCs should work. Accordingly, selection among them should be based primarily on tolerability.

105.4.4.3.2 Spironolactone.

Spironolactone [Aldactone] blocks a variety of steroid receptors, including those for aldosterone and sex hormones. Blockade of aldosterone receptors underlies the drug's use as a diuretic (see [Chapter 40](#)) as well as its use in heart failure (see [Chapter 47](#)). Blockade of androgen receptors underlies benefits in females with acne. As a rule, spironolactone is *added* to the regimen after an oral contraceptive has proved inadequate. This sequence makes sense. Why? Because spironolactone is teratogenic, and hence contraception should be implemented before taking the drug. Adverse effects include menstrual irregularities, breast tenderness, and hyperkalemia.

10... SUNSCREENS

Sunlight has multiple effects on the skin. In addition to promoting tanning, solar radiation can cause burns, premature aging of the skin, skin cancer, and immunosuppression. Sun exposure can also induce photosensitivity reactions to drugs. All of these effects are caused by ultraviolet (UV) radiation, and all can be greatly reduced by using a sunscreen.

105.5.1 Types of Ultraviolet Radiation: UVB and UVA

Solar UV radiation that reaches the earth's surface is classified by wavelength into two basic types: UVB (290 to 320 nm) and UVA (320 to 400 nm). UVA can be further subdivided into UVA2 (320 to 340 nm) and UVA1 (340 to 400 nm). Most (95%) of terrestrial UV radiation is UVA; only 5% is UVB. The intensity of UVA radiation is fairly constant from morning to evening and from one day to the next throughout the year. In contrast, UVB radiation is significant only between late spring and early fall, and, on any given day, is moderate in the morning and evening, and most intense around noon. UVA can penetrate glass; UVB can't.

TABLE 104-3 Properties of UVB and UVA Radiation

Property	Type of UV Radiation	
	UVB	UVA
Wavelength (nm)	290–320	320–400
Can penetrate glass	No	Yes
Skin penetration	Epidermis only	Epidermis/dermis
Effects on the skin:		
Burning	Major cause	Minor cause
Tanning	Major cause	Minor cause
Cancer	Major cause	Major cause
Photoaging		Sole cause
Photosensitive drug reactions		Sole cause

The dermatologic effects of UVB and UVA differ. UVA penetrates the epidermis and deep into the dermis. In contrast, UVB penetrates into the epidermis but goes no deeper. Tanning and sunburn are caused primarily by UVB. Because UVA penetrates much deeper than UVB, UVA is the primary cause of immunosuppression, photosensitive drug reactions, and photoaging of the skin (wrinkling, thickening, yellowing, breakdown of elastic fibers). Both UVA and UVB promote damage to DNA, and hence both can cause premalignant actinic keratoses, basal cell carcinoma, squamous cell carcinoma, and malignant and nonmalignant melanoma. Properties of UVA and UVB are summarized in [Table 104-3](#).

105.5.2 Benefits of Sunscreens

Sunscreens impede penetration of UV radiation to viable cells of the skin. As a result, sunscreens can protect against sunburn, photoaging of the skin, and photosensitivity reactions to certain drugs (eg, tricyclic antidepressants, phenothiazines, sulfonamides, sulfonylureas). Sunscreens can also protect against actinic keratoses and squamous cell carcinoma. Whether sunscreens protect against basal cell carcinoma and melanoma is unclear.

105.5.3 Compounds Employed as Sunscreens

There are two categories of sunscreens: *organic* screens (also known as *chemical* screens) and *inorganic* screens (also known as *physical* screens). Organic screens *absorb* UV radiation and

then dissipate it as heat. Inorganic screens *scatter* UV radiation. At this time, 17 compounds are FDA approved for use as sunscreens ([Fig. 104-2](#)).

105.5.3.1 Organic (Chemical) Screens.

Most (15) of the approved sunscreens are organic. Almost all of them absorb UVB, but only six absorb UVA. Of these six, five absorb UVA2, and only one—*avobenzone*—absorbs UVA1. Therefore, in order to provide protection against the full range of UV radiation, products must contain a mixture of compounds, one of which must be avobenzone. Products formulated with avobenzone include Aveeno Continuous Protection, Neutrogena Ultra Sheer Dry-Touch SPF 45, Sea & Ski Advanced Sunscreen, and Coppertone Sport.

105.5.3.2 Inorganic (Physical) Screens.

Physical screens act primarily as barriers to the sun's rays. Hence, rather than absorbing solar radiation, they *reflect and scatter* sunlight, thereby preventing penetration to the skin. Only two agents are employed as physical screens: *titanium dioxide* and *zinc oxide*. Preparations containing these compounds are especially useful for protecting limited areas (eg, nose, lips, tips of ears). In the formulations used today, titanium dioxide and zinc oxide are “micronized.” As a result, they are clear when applied to the skin, unlike older formulations, which were white.

1233
1234

Figure 104-2 Range of UVB and UVA protection conferred by FDA-approved sunscreens.

^{105.5.4} Sun Protection Factor

All sunscreen products are labeled with a sun protection factor (SPF). The SPF is an index of protection against UVB radiation. The SPF says nothing about UVA protection.

The SPF is determined by shining UV light on adjacent regions of protected and unprotected skin and recording the time required for erythema (redness) to develop in both areas. The SPF is calculated by dividing the time required for erythema to develop in the protected region by the time required for erythema to develop in the unprotected region. For example, if the unprotected region developed erythema in 15 minutes, and the protected region developed erythema in 150 minutes, the sunscreen would have an SPF of 10 (150 divided by 15). It should be noted that the methods for determining the SPF are not very precise. Hence, all products labeled with the same SPF may not provide an equal degree of protection.

You should appreciate that the relationship between SPF and protection against sunburn is not linear. That is, an SPF of 30 does not indicate twice as much protection as an SPF of 15. In fact, as the SPF increases, the increment in protection gets progressively smaller. For example, SPF 15 indicates 93% block of UVB, SPF 30 indicates 96.7% block, and SPF 40 indicates 97.5% block. Because SPF values above 30 provide only a small additional benefit, the FDA no longer allows companies to advertise high SPF values (eg, SPF 80). Instead products with an SPF greater than 30 can only be labeled as SPF 30+. However, this limit may be increased to 50+ (see below).

^{105.5.5} Water and Sweat Resistance

The FDA has defined two degrees of resistance to being washed off in water or by sweating. Products labeled as *water resistant* must retain their SPF for at least 40 minutes of activity in water. Products labeled as *very water resistant* must retain their SPF for at least 80 minutes of activity.

^{105.5.6} Adverse Effects of Sunscreens

Contact dermatitis and photosensitivity reactions can occur, especially with products that contain *para*-aminobenzoic acid (PABA) derivatives. PABA-containing products should be avoided by people with allergies to benzocaine, sulfonamides, or thiazides, all of which can cross-react with PABA.

^{105.5.7} Proposed Changes Regarding Sunscreen Testing and Labeling

The FDA is considering new regulations for testing and labeling sunscreen products. Importantly, the new rules would require testing for UVA protection (which is not done now)

and would require labels to display separate information on protection against UVB and UVA ([Fig. 104-3](#)). Also, the term *sun protection factor* (SPF) would be replaced with *UVB sunburn protection factor* (UVB SPF), to clearly indicate that SPF refers only to UVB radiation and only to protection against sunburn. Furthermore, the term *sunblock* would not be used. Rather, specific degrees of protection against UVB and UVA would be indicated as described below.

105.5.7.1 UVB Rating and Labeling.

The proposed rules regarding UVB protection would divide sunscreens into four groups as follows:

Low protection	UVB SPF 2–14
Medium protection	UVB SPF 15–29
High protection	UVB SPF 30–50
Highest protection	UVB SPF 50+

Specific UVB SPF values above 50 (eg, 75 or 90) would not be allowed. Why? Because current methodology does not permit determination of values above UVB SPF 50 that are either accurate or reproducible.

105.5.7.2 UVA Rating and Labeling.

The proposed rules regarding UVA protection would classify sunscreens using a 4-star rating system as follows:

Highest
protection

Assignment to a group would be based on *in vivo* as well as *in vitro* testing. Products that lack UVA protection would clearly state “no UVA protection.”

105.5.8 Safe Sunning

To protect against skin damage from sunlight, we should use a sunscreen, protective clothing, and common sense.

105.5.8.1 Using a Sunscreen Effectively.

Sunscreens must be used properly to achieve maximum benefit. The American Academy of Dermatology recommends using a sunscreen with coverage against both UVB and UVA. The SPF should be at least 15. Individuals who burn easily should use a higher

1234

1235

Figure 104-3 Proposed changes to sunscreen product labels. Note that the proposed new label indicates the degree of protection against UVB *and* UVA, whereas the current label only lists an SPF value, indicating the degree of protection against UVB, but not UVA. The words “Broad-Spectrum Protection” on the current label *imply* protection against UVA, but do not quantify just how much protection is conferred.

SPF. Protection is greatest when a sunscreen has been allowed to penetrate the skin in advance of exposure to the sun. Accordingly, it is recommended that sunscreens be applied at least 30 minutes prior to going outdoors; sunscreens containing PABA or padimate O should be applied up to 2 hours in advance. The amount applied is an important determinant of protection; 2 mg/cm² is considered adequate. Sunscreens should be re-applied after swimming and profuse sweating; failure to do so reduces the duration of protection. However, it is important to note that re-application will not extend the period of protection beyond that indicated by the SPF. That is, if treated skin can be expected to burn when sun exposure exceeds 2 hours, no amount of re-application can prevent burning if the duration of exposure exceeds the limit.

Environmental factors play a part in sunscreen use. The intensity of UVB radiation is greatest between the hours of 10:00 AM and 4:00 PM. Accordingly, the need for a sunscreen is correspondingly high during this time. Ultraviolet radiation can be reflected by painted surfaces, white sand, and snow, thereby augmenting total UV exposure. Accordingly, the contribution of reflected radiation should be considered when choosing a sunscreen. Clouds can filter out UV radiation. Nonetheless, the amount of UV light reaching the ground on a bright day with thin cloud cover can be as much as 80% of that reaching the ground on days that are sunny and clear. Ultraviolet radiation can penetrate at least several centimeters of clear water; swimmers should be made aware of this fact.

105.5.8.2 Other Protection Measures.

Sunscreens alone cannot completely protect against sun damage. Accordingly, to further reduce risk, you should wear sunglasses, protective clothing, and a wide-brimmed hat. In addition, common sense dictates avoiding sun exposure in the middle of the day, especially between 10:00 AM and 4:00 PM. If you must be outside at these times, try to stay in the shade.

TABLE 104-4 Treatments for Psoriasis

Topical Drugs
Glucocorticoids
Calcipotriene [Dovonex]
Tazarotene [Tazorac]
Anthralin [Dithro-Scalp, Psoriatec]
Salicylic acid
Tars
Systemic Drugs: Conventional Agents

Acitretin [Soriatane]
Cyclosporine [Neoral, others]
Systemic Drugs: Biologic Agents
T-Cell Antagonists
Alefacept [Amevive]
Efalizumab [Raptiva] [†]
Tumor Necrosis Factor Inhibitors
Adalimumab [Humira]
Etanercept [Enbrel]
Infliximab [Remicade]
Interleukin-12/23 Antagonist
Ustekinumab [*]
Phototherapy
Coal tar plus UVB irradiation
Photochemotherapy (PUVA therapy)

* Investigational in the United States.

† Voluntarily withdrawn in June 2009.

^{10...} PSORIASIS

^{105.6.1} Pathophysiology

Psoriasis is a common, chronic inflammatory disorder that follows an erratic course. The initial episode usually develops in early adulthood. Subsequent attacks may occur spontaneously or may be triggered by emotional stress, streptococcal pharyngitis (sore throat), or certain drugs, including lithium, beta blockers, antimalarials, and angiotensin-converting enzyme inhibitors. There is no cure for psoriasis, but symptoms can usually be controlled with medication. Drug-induced remission is common and may last from a few weeks to many years.

Psoriasis has varying degrees of severity. Mild disease manifests as red patches covered with silvery scales; lesions typically appear on the scalp, elbows, knees, palms, and soles. Severe disease may involve the entire skin surface and mucous membranes; patients may develop superficial pustules, high fever, leukocytosis, and painful fissuring of the skin.

Symptoms result from two processes: accelerated maturation of epidermal cells (keratinocytes) and excessive activity of inflammatory cells. In recent years, it has become clear that inflammatory T cells (T lymphocytes) play a central role in the development and maintenance of psoriatic plaques. Hence, it now appears that psoriasis is primarily an inflammatory disorder, and that excessive proliferation of keratinocytes is a secondary response.

^{105.6.2} Overview of Treatment

Psoriasis can be treated with topical drugs, systemic drugs, or phototherapy. Several of the drugs employed suppress proliferation of keratinocytes. However, most antipsoriatic drugs suppress the activity of inflammatory cells. Treatment options are summarized in [Table 104-4](#).

Treatment is based on symptom severity. For mild psoriasis, topical glucocorticoids are usually adequate; keratolytic agents (eg, salicylic acid) may be useful adjuncts to steroid therapy.

Calcipotriene may also be tried. For patients with moderate symptoms, coal tar or anthralin may be added to the regimen. Topical therapy with tar and anthralin can be enhanced by exposing the skin to UVB light. Treatment options for moderate to severe psoriasis include phototherapy or systemic treatment with methotrexate, acitretin, alefacept, and other drugs.

1235

1236

105.6.3 Topical Drugs for Psoriasis

105.6.3.1 Glucocorticoids

In the United States, glucocorticoids are the most commonly used topical drugs for psoriasis. Benefits derive from suppressing the activity of inflammatory cells. Preparations with super-high potency are employed where plaques are thickest. However, super-high-potency agents should not be applied to the face, groin, axilla, or genitalia. Why? Because skin in these regions is especially vulnerable to glucocorticoid-induced atrophy.

105.6.3.2 Calcipotriene

Calcipotriene [Dovonex], an analog of vitamin D₃, is indicated for mild to moderate psoriasis. Responses are equal to those achieved with medium-potency topical glucocorticoids. Improvement may take 1 to 2 months to develop. Benefits derive from inducing epidermal cell differentiation and inhibiting keratinocyte proliferation. The most common adverse effect is local irritation. Unlike glucocorticoids, calcipotriene does not cause thinning of the skin. At doses twice the weekly recommended maximum of 100 gm, calcipotriene has caused hypercalcemia. Long-term safety has not been established.

105.6.3.3 Tazarotene

Tazarotene [Tazorac] is a vitamin A derivative indicated for topical therapy of mild to moderate psoriasis. Following application to the skin, tazarotene is rapidly converted to tazarotenic acid, its active form. Tazarotenic acid binds with specific retinoic acid receptors, and thereby normalizes differentiation and proliferation of epidermal cells. In clinical trials, application of a 0.1% tazarotene gel once daily for 12 weeks produced a significant reduction in lesions in 50% to 70% of patients. Benefits were about equivalent to those seen with 0.05% fluocinonide, a high-potency topical glucocorticoid. Tazarotenic acid stays in the skin long after application of tazarotene has stopped. As a result, benefits may persist for several months. Use of tazarotene for acne is discussed above.

Adverse effects are limited largely to the skin. The most common local reactions (10% to 30%) are itching, burning, stinging, dry skin, and redness. Less common effects (1% to 10%) include rash, desquamation, contact dermatitis, inflammation, fissuring, and bleeding. Tazarotene sensitizes the skin to sunlight. Accordingly, patients should be advised to use a sunscreen and wear protective clothing.

Tazarotene gel is available in two concentrations: 0.05% and 0.1%. The gel is applied once daily in the evening. No more than 20% of the body surface area should be covered. Wet skin should be dried before application.

105.6.3.4 Anthralin

Anthralin is indicated only for topical treatment of psoriasis. The drug inhibits DNA synthesis and thereby suppresses proliferation of hyperplastic epidermal cells.

Anthralin may cause local irritation, especially when applied in concentrations above 1%. Erythema (redness) may develop in normal skin adjacent to areas of treatment. Severe conjunctivitis can develop following contact with the eyes. Systemic toxicity has not been documented. Anthralin preparations can stain clothing, skin, and hair.

Anthralin is supplied as a 0.5% and 1% cream. In conventional therapy, the drug is applied to lesions at bedtime and allowed to remain in place overnight. Stains can be avoided by wearing old clothing and by covering treated areas with a dressing. Trade names for anthralin products are Dritho-Scalp and Psoriatec.

105.6.3.5 Tars

Tars suppress DNA synthesis, mitotic activity, and cell proliferation. Coal tar is the tar employed most frequently. Preparations that contain juniper tar, birch tar, and pine tar are also available. Tar-containing products (eg, shampoos, lotions, creams) are used to treat psoriasis and other chronic disorders of the skin. Tars have an unpleasant odor and can cause irritation, stinging, and burning. They may also stain the skin and hair. Systemic toxicity does not occur.

105.6.4 Systemic Drugs for Psoriasis: Conventional Agents

The conventional systemic drugs—methotrexate, acitretin, and cyclosporine—are oral agents that provide effective therapy for psoriasis, but also pose a risk of serious harm. Accordingly, these drugs are reserved for patients with moderate to severe psoriasis that has not responded to safer treatments. To reduce risk, systemic drugs can be alternated with phototherapy.

105.6.4.1 Methotrexate

The basic pharmacology of methotrexate [Trexall, Rheumatrex] is discussed in [Chapter 101](#) (Anticancer Drugs I: Cytotoxic Agents). Consideration here is limited to treatment of psoriasis.

105.6.4.1.1 Actions and Use in Psoriasis.

Methotrexate is a cytotoxic agent that shows some selectivity for tissues with a high growth fraction (ie, tissues with a large percentage of actively dividing cells). Benefits in psoriasis result from reduced proliferation of epidermal cells. The biochemical mechanisms underlying suppression of cell growth and division are discussed in [Chapter 101](#). Methotrexate is highly toxic and should be used only in patients with severe, debilitating psoriasis that has not responded to safer therapy.

105.6.4.1.2 Adverse Effects.

Methotrexate is administered systemically, and toxicity can be severe. Death has occurred. Patients should be fully informed of the risks of treatment. Close medical supervision is required. Gastrointestinal effects (diarrhea, ulcerative stomatitis) are the most frequent reasons for interrupting therapy. Blood dyscrasias (anemia, leukopenia, thrombocytopenia) from bone marrow suppression are an additional major concern. With prolonged use, even at relatively low doses, methotrexate can cause significant harm to the liver. Accordingly, hepatic function must be monitored; a liver biopsy is the best method for assessing injury. Methotrexate can cause congenital anomalies and fetal death, and hence is contraindicated during pregnancy.

105.6.4.1.3 Dosage and Administration.

Methotrexate may be administered PO, IM, or IV. Various dosing schedules have been developed. In one schedule, the drug is administered once a week as a single large dose (10 to 25 mg). In an alternative schedule, three smaller doses (2.5 to 5 mg) are administered at 12-hour intervals; this dosing sequence is repeated weekly. Regardless of the schedule chosen, dosages must be individualized.

105.6.4.2 Acitretin

Acitretin [Soriatane] is the principal active metabolite of etretinate [Tegison], a highly toxic drug that has been withdrawn. The major difference between the two drugs is pharmacokinetic: Whereas etretinate has a very long half-life (120 days), the half-life of acitretin is much shorter (only 49 hours). Accordingly, acitretin is cleared from the body much faster than etretinate. Although acitretin is less dangerous than etretinate, it still can cause serious harm, especially injury to the liver and developing fetus.

105.6.4.2.1 Mechanism of Action.

Acitretin acts on epithelial cells to inhibit keratinization, proliferation, and differentiation. These actions probably contribute to its beneficial effects. Benefits may also derive from anti-inflammatory and immunomodulatory actions.

105.6.4.2.2 Therapeutic Use.

Acitretin is indicated for severe psoriasis, including erythrodermic and generalized pustular types. Efficacy is equivalent to that of etretinate. In clinical trials, the drug produced a 60% to 70% reduction in the severity and area of symptoms. The relapse rate was 40% at 12 weeks after termination of treatment. Because side effects are very common and sometimes severe, acitretin should be reserved for patients who have not responded to safer drugs.

105.6.4.2.3 Pharmacokinetics.

Administration is oral, and absorption is enhanced by food. In the blood, acitretin is 99.9% bound to plasma proteins. The drug undergoes extensive metabolism followed by excretion in the urine and bile. Its half-life is 49 hours. If taken with alcohol, acitretin will be converted to etretinate.

105.6.4.2.4 Adverse Effects.

Adverse effects are very common. Hair loss and skin peeling occur in 50% to 75% of patients. Other dermatologic effects (dry skin, nail disorders, pruritus) occur in 25% to 50% of patients. Mucous membranes are affected, causing rhinitis (25% to 50%), inflammation of the lips (25% to 50%), dry mouth (10% to 25%), nosebleed (10% to 25%), and gingival bleeding, gingivitis, and stomatitis (1% to 10%). Other common reactions include erythematous rash (10% to 25%), bone and joint pain (10% to 25%), spinal hyperostosis (10% to 25%), dry eyes (10% to 25%), and paresthesias (10% to 25%). In addition, acitretin can elevate plasma triglycerides and reduce levels of HDL cholesterol (good cholesterol). Signs of liver damage (elevation of aminotransferase activity) develop in one-third of patients, but normally resolve when treatment is stopped.

105.6.4.2.5 Drug Interactions.

Alcohol promotes conversion of acitretin to etretinate, and can thereby greatly prolong the risk of teratogenic effects (see below). Accordingly, women of child-bearing age should be warned against drinking alcohol. Acitretin can reduce the efficacy of progestin-only oral contraceptives, and hence other forms of contraception are preferred. Because acitretin is a

derivative of vitamin A, combining it with vitamin A supplements may pose a risk of vitamin A toxicity. Both acitretin and tetracycline can cause pseudotumor cerebri (intracranial hypertension), and therefore combining the drugs is not recommended. In addition, acitretin should not be combined with methotrexate and other drugs that can damage the liver.

1236

1237

105.6.4.2.6 **Contraindication: Pregnancy.**

Acitretin is embryotoxic and teratogenic, and therefore must not be used during pregnancy.

The drug is classified in FDA Pregnancy Risk Category X: The risks of use during pregnancy clearly outweigh any possible benefits. Major human fetal abnormalities that have been reported include encephalocele (hernia of the brain through a skull defect), reduced cranial volume, facial malformation, cardiovascular defects, absence of terminal phalanges, and malformations of the hip, ankles, and forearms.

Before acitretin is given to women of reproductive age, pregnancy should be ruled out and *two* reliable methods of contraception implemented. Contraception should be initiated at least 1 month prior to treatment and should continue for at least 3 years after treatment has ceased. Women should be thoroughly counseled about the potential for fetal harm. If pregnancy occurs, acitretin should be discontinued immediately, and possible termination of pregnancy should be discussed.

105.6.4.2.7 **Preparations, Dosage, and Administration.**

Acitretin [Soriatane] is available in 10- and 25-mg capsules for oral dosing. The dosage for psoriasis is 25 or 50 mg once daily, taken with a meal to facilitate absorption. As a rule, administration should cease when lesions have sufficiently resolved.

105.6.4.3 **Cyclosporine**

Cyclosporine [Neoral, others] is a powerful immunosuppressant that inhibits proliferation of B cells and T cells. In patients with psoriasis, the drug produces rapid improvement.

Unfortunately, cyclosporine can cause kidney damage and other serious harm, and hence should be used only after safer drugs have failed. The basic pharmacology of cyclosporine is presented in [Chapter 68](#) (Immunosuppressants).

105.6.5 **Systemic Drugs for Psoriasis: Biologic Agents**

Like the conventional systemic drugs, the biologic agents are reserved for patients with moderate to severe psoriasis that has not responded to other treatments. At this time, four biologic agents are in general use, and a fifth agent—ustekinumab—is nearing approval. One of these drugs—alefacept—decreases the activity of T cells. Three others—etanercept, infliximab, and

adalimumab—block tumor necrosis factor (TNF). Ustekinumab inhibits interleukin-12 (IL-12) and interleukin-23 (IL-23). All five drugs suppress immune function, and thereby increase the risk of serious infection. However, these drugs don't cause the serious acute toxicities—hepatotoxicity and nephrotoxicity—seen with the conventional systemic drugs. All of the biologic agents are administered by injection.

105.6.5.1 T-Cell Antagonists

105.6.5.1.1 Alefacept.

Alefacept [Amevive], approved in January 2003, was the first biologic therapy for psoriasis. The drug is moderately effective, and has produced prolonged remission in some patients. Alefacept causes few immediate adverse effects, but over time may increase the risk of serious infections and perhaps cancer. Although alefacept is fairly effective, it is also expensive (treatment costs \$12,000 or more a year) and inconvenient (treatment requires IM injections and weekly blood tests), and possible long-term toxicity is unknown.

105.6.5.1.1.1 Actions and Therapeutic Use.

Alefacept reduces the number and activity of memory CD4⁺ T lymphocytes, which are the principal mediators of inflammation in psoriasis. Benefits take about 2 months to develop, and correlate directly with reduced T-cell counts. Alefacept is approved for adults with moderate to severe psoriasis. In one trial, two courses of IV therapy reduced symptom intensity by 50% or more in 71% of patients, and by 75% or more in 40% of patients. Response duration ranged from about 7 months to more than 12 months. Alefacept has not been compared directly with conventional systemic agents (eg, methotrexate, acitretin).

105.6.5.1.1.2 Adverse Effects.

The most common adverse effect is chills, which develop in about 6% of patients receiving alefacept IV (versus 1% of patients receiving IV placebo). Less common effects are pharyngitis, dizziness, cough, pruritus, myalgia, chills, inflammation, and injection-site pain.

Alefacept produces a dose-dependent decrease in circulating T cells, and can thereby cause *lymphopenia*, a condition that increases the risk of *infection*. Accordingly, alefacept should be avoided in patients with clinically important infections, and should be used with caution in patients with chronic infection or a history of recurrent infection. If a serious infection develops, the drug should be discontinued. To minimize infection risk, CD4⁺ lymphocyte counts must be monitored (see below).

Alefacept may increase the risk of *cancer*. In studies with monkeys, the drug was associated with B-cell hyperplasia and B-cell lymphoma. In one clinical trial, the incidence of malignancy was 1.3% in patients receiving alefacept, versus 0.5% in those receiving placebo. Alefacept should be avoided in patients with a history of systemic malignancy, and should be discontinued if malignancy develops.

Alefacept is contraindicated for people with HIV infection. Why? Because HIV and alefacept both decrease CD4+ T-cell counts. Hence there is concern that alefacept may accelerate progression of HIV disease.

105.6.5.1.1.3 Drug Interactions.

There have been no formal studies on the interaction of alefacept with other drugs. However, common sense dictates that alefacept not be combined with other drugs that can reduce T-cell number.

105.6.5.1.1.4 Monitoring.

Counts of CD4+ T cells must be determined at baseline and before each alefacept dose. If the count is below 250 cells/mL, dosing should be postponed. If the count remains below 250 cells/mL for more than 1 month, alefacept should be discontinued.

105.6.5.1.1.5 Preparations, Dosage, and Administration.

Alefacept [Amevive] is supplied as a 15-mg powder to be reconstituted with the supplied diluent for IM administration. The initial dosing schedule is 15 mg once a week for 12 weeks. If needed, the 12-dose series can be repeated—but no sooner than 12 weeks after completing the first series, and provided T-cell counts are in the normal range. There is no experience with giving a third series.

105.6.5.1.1.6 Cost.

Alefacept is expensive. A 12-week IM course costs about \$12,000. If two courses are needed, the cost is doubled. Weekly monitoring of CD4+ T cells can raise the cost by another \$8000. In comparison, treatment with oral methotrexate costs only \$500 to \$800 a year.

105.6.5.1.2 Efalizumab.

Efalizumab [Raptiva], was approved in October 2003 and withdrawn in June 2009, owing to a risk of progressive multifocal leukoencephalopathy (PML). Efalizumab is an antibody with

actions similar to those of alefacept. Both drugs are moderately effective against psoriasis, and both increase the risk of infection and possibly cancer.

105.6.5.1.2.1 Mechanism of Action.

Efalizumab is a monoclonal antibody that inhibits the activity of T lymphocytes, which are important mediators of inflammation in psoriasis. Specifically, the drug binds with CD11a (a protein on the surface of T cells), and thereby inhibits (1) T-cell activation, (2) adhesion of T cells to endothelial cells, and (3) migration of T cells to areas of inflammation, including psoriatic skin lesions. Because CD11a is also present on the surface of B lymphocytes, monocytes, neutrophils, and natural killer cells, efalizumab can inhibit the activation, adhesion, and migration of these immune-related cells, thereby increasing the risk of infection.

105.6.5.1.2.2 Therapeutic Use.

Efalizumab is approved for moderate to severe psoriasis in adults. In a 12-week clinical trial, about 30% of patients achieved a good response. Although efalizumab and alefacept have not been compared directly, response rates appear about equal. However, the time to relapse following discontinuation is very different: about 3 months for efalizumab versus 7 to 12 months for alefacept.

105.6.5.1.2.3 Adverse Effects.

In clinical trials, 29% of patients experienced flu-like symptoms—headache, chills, fever, nausea, and myalgia—following the first one or two doses. By the third dose, these reactions generally subside.

Efalizumab poses a small risk of *thrombocytopenia*. Some patients have experienced heavy bleeding. The decline in platelets usually begins 8 to 12 weeks after the first dose.

Monitoring of platelet counts is recommended at baseline and periodically throughout the treatment period.

Very rarely, patients develop *hemolytic anemia*. However, a causal relationship has not been established. Nonetheless, if hemolytic anemia develops, efalizumab should be discontinued.

Owing to its immunosuppressant actions, efalizumab can increase the risk of *serious infections*, including bacterial sepsis, viral meningitis, invasive fungal disease, and PML, an untreatable infection of the brain. Accordingly, efalizumab should not be given to patients with an ongoing serious infection, and should be used with caution in patients with

a history of recurrent infection. If an infection develops, the prescriber should be notified immediately. Combining efalizumab with another immunosuppressant can increase the risk of infection, and hence should be avoided. Before receiving efalizumab, patients should have gotten all of their age-appropriate vaccinations.

In clinical trials, 0.7% of patients experienced *worsening of psoriasis*. Some required hospitalization. Worsening of symptoms may occur while efalizumab is being used or after treatment has stopped.

Like other immunosuppressants, efalizumab may pose a small risk of *malignancy*. However, whether the drug actually promotes cancer is unknown. Nonetheless, efalizumab should be used with caution in patients at high risk for malignancy or with a history of malignancy, and should be discontinued if malignancy develops.

Efalizumab is in *FDA Pregnancy Risk Category C*: Animal studies show a risk of fetal harm, but no controlled studies have been done in women. Until more is known, use by pregnant women is not recommended.

1237

105.6.5.1.2.4

Preparations, Dosage, and Administration.

1238

Prior to being withdrawn, efalizumab was supplied in a kit containing (1) 150 mg of powdered efalizumab in a single-use vial, (2) 1.3 mL of diluent (sterile water for injection) in a pre-filled, single-use syringe, and (3) two 25-gauge $\frac{5}{8}$ -inch needles plus two alcohol prep pads. When the powdered drug and diluent are mixed, they form a 100-mg/mL solution, which should be injected immediately. Treatment consists of an initial conditioning dose (0.7 mg/kg subQ) to help reduce the incidence of early side effects, followed by weekly maintenance doses (1 mg/kg subQ, not to exceed 200 mg/dose). Injections are made into the thigh, abdomen, buttocks, or upper arm.

105.6.5.2 Tumor Necrosis Factor Inhibitors

Drugs that inhibit tumor necrosis factor (TNF) can suppress immune function, and can thereby reduce inflammation in patients with psoriasis. Three TNF inhibitors are approved for psoriasis: adalimumab [Humira], etanercept [Enbrel], and infliximab [Remicade]. Because of immunosuppression, all three drugs pose a risk of serious opportunistic infections. Dosages for psoriasis are as follows: adalimumab, 80 mg subQ initially, then 40 mg subQ weekly thereafter; etanercept, 25 mg subQ twice a week; and infliximab, 3 mg/kg, infused IV over 2 or more hours, on days 0, 2, and 6, and then once every 8 weeks thereafter. The basic pharmacology of these drugs is presented in [Chapter 72](#) (Drug Therapy of Rheumatoid Arthritis).

105.6.5.3 Ustekinumab

Ustekinumab, also known as CNTO 1275, is an investigational immunosuppressant under study for psoriasis, arthritis, and multiple sclerosis. The drug is a monoclonal antibody that can block IL-12 and IL-23, components of the immune system that help mediate inflammation. In one clinical trial, two-thirds of patients experienced at least a 75% reduction in symptoms. Like other biologic therapies for psoriasis, ustekinumab is administered by injection. However, since injections are made just once every 12 weeks, ustekinumab is more convenient than the other biologic therapies. The major concern with ustekinumab is the possibility of promoting cancer.

105.6.6 Phototherapy

105.6.6.1 Coal Tar Plus Ultraviolet B Irradiation

This procedure involves sequential treatment with coal tar followed by UV radiation. In the first step, affected regions are covered with 1% coal tar ointment for 8 to 10 hours, after which the coal tar is washed off. In the second step, the area is exposed to short-wave UV radiation (ultraviolet B, UVB). This procedure is very safe and produces remission in 80% of patients. Unfortunately, treatment is expensive and time consuming (up to 30 treatments are needed), and patients dislike being coated with smelly coal tar.

105.6.6.2 Photochemotherapy (PUVA Therapy)

Photochemotherapy combines the use of long-wave UV radiation (ultraviolet A, UVA) with *methoxsalen*, an orally administered photosensitive drug. Methoxsalen belongs to a chemical family known as *psoralens*. In response to UVA light shined on the skin, methoxsalen is thought to undergo a photochemical reaction with DNA, resulting in the formation of a DNA-psoralen complex. This alteration in DNA structure is thought to underlie the ability of photochemotherapy to decrease proliferation of epidermal cells. Adverse effects associated with the procedure include pruritus, nausea, and erythema. In addition, the process may accelerate aging of the skin and may increase the risk of skin cancer. Photochemotherapy is indicated for patients with extensive, active psoriasis who have not responded adequately to more conventional therapy. An alternative name for photochemotherapy is *PUVA therapy*; PUVA is an abbreviation derived from *psoralen* and *ultraviolet A*.

^{10...} DRUGS FOR ACTINIC KERATOSES

Actinic keratoses (AKs) are rough, scaly, red or brown papules caused by chronic exposure to sunlight. Lesions typically develop on the face, scalp, forearms, and backs of the hands. A small percentage (0.25% to 1% per year) evolve into squamous cell carcinoma. However, although the *percentage* is small, the *absolute amount* is large: In the United States, nearly half of all skin cancers (about 500,000 cases) begin as AKs. AK treatment consists of topical drugs—fluorouracil, diclofenac, imiquimod, and aminolevulinic acid—and physical interventions: cryotherapy, curettage, excision, and laser resurfacing. Of these options, cryotherapy (freezing with liquid nitrogen) is used most, owing to its speed, simplicity, and effectiveness.

^{105.7.1} Fluorouracil

The basic pharmacology of fluorouracil [Carac, Efudex, Fluoroplex] is discussed in [Chapter 101](#) (Anticancer Drugs I: Cytotoxic Agents). Discussion here is limited to treatment of dermatologic disorders.

^{105.7.1.1} Actions and Uses in Dermatology.

Fluorouracil is indicated for topical treatment of *multiple actinic keratoses* and *superficial basal cell carcinoma*. Cytotoxic effects result from disruption of DNA and RNA synthesis. A course of topical treatment elicits the following sequence of responses: (1) mild inflammation; (2) severe inflammation, often with burning, stinging, and vesicle formation; (3) tissue disintegration, characterized by erosion, ulceration, and necrosis; and (4) healing. Although fluorouracil is only applied for 2 to 6 weeks, the events just described may require 3 or more months for completion. Treatment is effective in over 90% of those who can tolerate a full course.

^{105.7.1.2} Adverse Effects.

Among the more frequent reactions are itching, burning, rash, inflammation, and increased sensitivity to sunlight. Intense, burning pain develops occasionally. Darkening of the skin is rare. Absorption is insufficient to cause systemic toxicity.

^{105.7.1.3} Preparations and Administration.

Topical fluorouracil is available under three trade names: *Carac* (microspheres in a 0.5% cream), *Efudex* (5% cream, 2% and 5% solutions), and *Fluoroplex* (1% cream). Carac is applied once daily; Efudex and Fluoroplex are applied twice daily. Treatment should continue

until a stage-three response (tissue disintegration) develops, usually within 2 to 6 weeks. Complete healing may not occur for another 1 to 2 months.

105.7.2 Diclofenac Sodium

Diclofenac sodium [Solaraze], in a 3% gel, was the first nonsteroidal anti-inflammatory drug (NSAID) approved for topical use. The only indication for Solaraze is AK.* Topical diclofenac is better tolerated than fluorouracil, but is less effective and treatment takes longer. In clinical trials, twice-daily application for 60 to 90 days produced complete clearing in 50% of patients. The mechanism underlying benefits is unknown. The most common side effects are dry skin, itching, redness, and rash at the site of application. Diclofenac may sensitize the skin to UV radiation, and hence patients should avoid sunlamps and minimize exposure to sunlight. Systemic absorption is low (10%), and therefore the risk of GI injury is much less than with oral diclofenac and other NSAIDs.

* Two other topical formulations of diclofenac, sold as Voltaren Gel and Flector, are available to relieve musculoskeletal pain (see [Chapter 70](#)).

105.7.3 Imiquimod

Imiquimod 5% cream [Aldara], originally developed for venereal warts (see below), was approved for AK in 2004. Benefits derive from stimulating innate and cell-mediated immunity. Imiquimod requires a prescription, but is applied at home (twice weekly at bedtime, and then washed off in the morning). Imiquimod is better tolerated than fluorouracil, but less effective, causing complete clearance in only 45% of patients, compared with 90% for fluorouracil. Also, treatment takes much longer (16 weeks vs. 2 to 6 weeks with fluorouracil). In clinical trials, 33% of patients experienced local reactions: redness, swelling, sores, blisters, itching, burning, scabbing, and crusting. Of note, lesion clearance correlated with the intensity of side effects, suggesting that an inflammatory reaction is needed to produce a clinical response. Imiquimod increases sensitivity to UV radiation, and hence patients should minimize sun exposure, use a sunscreen, and wear protective clothing.

105.7.4 Aminolevulinic Acid Plus Blue Light

Topical aminolevulinic acid [Levulan Kerastick], in conjunction with blue light photoactivation, is an alternative therapy for AKs of the face and scalp. Treatment takes place in two steps. First, the prescriber applies a 20% solution of aminolevulinic acid to AK lesions. Fourteen to 18 hours later, the prescriber photoactivates the drug by exposing lesions to 1000 seconds of blue light, using the Blu-B Blue Light supplied by the manufacturer. In clinical trials, 66% of patients experienced complete clearing by 8 weeks after a single treatment, and 77% of patients

experienced clearing of 75% or more. The mechanism underlying benefits is complex and incompletely understood. Local effects—burning, stinging, redness, and edema—occurred in nearly all patients. Because aminolevulinic acid is light sensitive, patients should protect treated areas from exposure to sunlight and bright indoor light prior to blue light exposure. The best protection is a wide-brimmed hat; sunscreens won't help.

1238

^{10...} DRUGS FOR ATOPIC DERMATITIS (ECZEMA)

1239

Atopic dermatitis, also known as eczema, is a chronic inflammatory skin disease seen primarily in children. The condition is characterized by dry, scaly skin and intense pruritus that often leads to scratching and rubbing, which in turn can lead to erythema, abrasions, rash, erosions with an exudate, and increased susceptibility to skin infection. The underlying cause is abnormal activity of T lymphocytes. First-line therapy consists of moisturizers and topical glucocorticoids. Unfortunately, the glucocorticoids can cause skin atrophy, hypopigmentation, telangiectasis (permanent focal red lesions), and, in high doses, possible systemic effects (eg, adrenal suppression). If topical glucocorticoids are insufficient, patients may be treated with systemic immunosuppressants. Among these are methotrexate, cyclosporine [Sandimmune, others], azathioprine [Imuran], and oral glucocorticoids, all of which can cause serious side effects. A sedating antihistamine can help control itching and can facilitate sleeping at night.

^{105.8.1} Topical Immunosuppressants

Two topical immunosuppressants—tacrolimus and pimecrolimus—are approved for atopic dermatitis. These drugs represent an alternative to glucocorticoids for topical therapy. Unfortunately, both agents may pose a risk of skin cancer and lymphoma. Because of this potential for serious harm, tacrolimus and pimecrolimus should be reserved for patients who have not responded to safer drugs.

^{105.8.1.1} Tacrolimus Ointment.

Tacrolimus [Protopic], an immunosuppressant available as Prograf for preventing organ transplant rejection (see [Chapter 68](#)), is now available as an ointment for moderate to severe atopic dermatitis.

Tacrolimus relieves symptoms by attenuating local immune responses. Specifically, the drug suppresses the activity of T cells and decreases the release of inflammatory mediators from cutaneous mast cells and basophils. The result is reduced inflammation.

Systemic absorption of topical tacrolimus is low, and gets even lower as the skin heals. Absolute bioavailability is less than 0.05%. Blood levels of tacrolimus are usually low.

Tacrolimus ointment is generally well tolerated. The most common side effects are erythema, pruritus, and burning sensations at the application site. As the skin heals, these local reactions abate. In children, tacrolimus may increase the risk of varicella-zoster infection. Adverse effects associated with *systemic* tacrolimus (nephrotoxicity, neurotoxicity, hypertension, diarrhea, nausea) have not occurred with topical therapy. Unlike topical glucocorticoids, tacrolimus does not cause thinning of the skin.

There is concern that tacrolimus may pose a risk of cancer. The drug increases the incidence of skin cancer in laboratory animals exposed to UV light. In mice, tacrolimus increases the incidence of lymphoma. There have been reports of skin cancer and lymphoma in humans, although a causal relationship has not been established. To reduce any risk of skin cancer, patients should protect treated areas from direct sunlight, and should avoid sunlamps and tanning beds.

Tacrolimus ointment [Protopic] is available in two concentrations: 0.03% and 0.1%. Adults may use either formulation; children should use the 0.03% formulation. All patients should apply a thin layer twice daily. Occlusive dressings should be avoided.

105.8.1.2 Pimecrolimus Cream.

Pimecrolimus 1% cream [Elidel] is a topical immunosuppressant approved for mild to moderate atopic dermatitis. The drug is very similar to tacrolimus with regard to mechanism, therapeutic effects, and adverse effects. In clinical trials, twice-daily application for 3 weeks reduced signs and symptoms of eczema by 72%. Initial improvement could be seen in 2 days. Pimecrolimus may be less effective than topical glucocorticoids. Although studies comparing pimecrolimus directly with tacrolimus have not been done, clinical efficacy of the drugs appears similar.

Pimecrolimus is generally well tolerated. The most common adverse effects are erythema, pruritus, and burning sensations at the application site, especially during the first few days of treatment. As with tacrolimus, there have been reports of skin cancer and lymphoma, but a causal relationship has not been established. Like tacrolimus, pimecrolimus sensitizes the skin to UV light, and hence patients should use a sunscreen and should limit exposure to natural and artificial sunlight. Systemic absorption of pimecrolimus is minimal; in clinical trials, blood levels were at or below the limit of detection.

^{10...} AGENTS USED TO REMOVE WARTS

Warts are small, benign tumors that form in the skin and mucous membranes. They are caused by infection of squamous epithelial cells with human papillomavirus (HPV), of which there are roughly 100 types. Most warts resolve spontaneously within a few months, but some can last for years. Discussion below focuses primarily on management of venereal warts.

^{105.9.1} Venereal Warts

Venereal warts form around the cervix, vulva, urethra, glans penis, and anus and anal canal. The majority are caused by two types of HPV, known as HPV-6 and HPV-11. Two other types—HPV-16 and HPV-18—are responsible for most cervical cancers. As discussed in [Chapter 67](#) (Childhood Immunization), an HPV vaccine, sold as *Gardasil*, can protect against all four HPV types, and hence can help prevent venereal warts as well as cancer of the cervix. An investigational vaccine, known as *Cervarix*, only protects against HPVs 16 and 18, and hence can help prevent cervical cancer but not venereal warts.

Infection with HPV can be transmitted by sexual contact. Individuals with anogenital warts should be warned that they can transmit the infection to sexual partners. Partners of infected individuals should be examined for warts. Use of a condom can reduce the risk of transmission.

Genital warts can be removed in two basic ways: with topical drugs or with physical measures: cryotherapy (freezing), electrodesiccation, laser surgery, and conventional surgery. Physical measures are much faster than drugs but are also more painful. Neither approach—drugs or physical measures—can eradicate the virus. Hence, even after successful wart removal, the virus remains.

The drugs used to remove venereal warts can be divided into two groups: agents that must be administered by a healthcare provider and agents that can be applied at home. With both groups, application is done repeatedly until the warts disappear. Provider-applied drugs include *podophyllin*, *trichloroacetic acid*, and *bichloroacetic acid*. Drugs for home application are *podofilox*, *imiquimod*, and *kunecatechins*. All of these drugs act slowly, and they all cause local irritation. The pharmacology of four topical drugs is discussed below.

^{105.9.1.1} Podophyllin

Podophyllin (podophyllum resin) [Podocon-25, Podofin] is used primarily for perianal and venereal warts. The drug is not very effective against common warts. Podophyllin is a mixture of resins from the May apple or mandrake (*Podophyllum peltatum* Linne). The active ingredient in the resin is *podophyllotoxin*, a compound that inhibits synthesis of DNA and

mitosis. These actions eventually lead to cell death and erosion of warty tissue. Formulations employed to remove warts contain 25% podophyllum resin. These preparations are highly caustic and should be applied only by a trained clinician. To minimize the risk of toxicity from systemic absorption, the resin should be washed off with alcohol or soap and water a few hours after application. Each treatment should be limited to a small surface area and to a small number of warts.

Podophyllin can be absorbed in amounts sufficient to cause systemic toxicity. Potential reactions include central and peripheral neuropathy, kidney damage, and blood dyscrasias. These effects are most likely when the drug is applied to large areas in excessive amounts. Podophyllin is teratogenic and must not be used during pregnancy.

Podophyllin is supplied in a 25% solution for topical use. Application should be limited to small areas. The drug should not be applied to moles or birthmarks, nor should it be applied to warts that are bleeding or friable (easily crumbled) or that have undergone recent biopsy. When used to remove venereal warts, podophyllin should be washed off 1 to 6 hours after application. Treatment may be repeated at weekly intervals for up to 4 weeks.

105.9.1.2 Imiquimod, Podofilox, and Kunecatechins

Imiquimod, podofilox, and kunecatechins represent alternatives to podophyllin for topical therapy of external genital and perianal warts. Like podophyllin, these drugs require a prescription. However, in contrast to podophyllin, which must be applied by a clinician, these drugs can be applied at home by the patient, and hence are more convenient than podophyllin.

105.9.1.2.1 Imiquimod.

Imiquimod 5% cream [Aldara] stimulates production of interferon alpha, tumor necrosis factor, and several interleukins, and thereby intensifies immune responses to HPV, the virus that causes venereal warts. Imiquimod has no direct antiviral effects of its own. Principal adverse effects are erythema, erosion, and flaking at the site of administration. Local itching, burning, and pain may occur too. Imiquimod undergoes minimal absorption, and hence systemic effects are usually absent. The drug is applied at bedtime and should be washed off in the morning. Application is done 3 times a week for 16 weeks, or until the warts are gone—whichever comes first. Use of imiquimod for actinic keratoses is discussed above.

105.9.1.2.2 Podofilox.

Like podophyllin, podofilox [Condylox] inhibits mitosis. Whether this action underlies beneficial effects (erosion of warty tissue) is unknown. Podofilox is supplied as a 0.5% gel or

1239

1240

0.5% solution to be applied twice daily for 3 consecutive days followed by 4 days off. This pattern is repeated 4 times or until the warts are gone—whichever comes first. Patients should wash their hands before and after applying the drug. However, unlike imiquimod, podofilox needn't be washed from the site of application. Treatment frequently causes local inflammation, burning, erosion, pain, itching, and bleeding. These can be minimized by limiting the application area to 10 cm², applying no more than 0.5 gm/day, and avoiding application to normal skin. Podofilox causes more discomfort than imiquimod, but works faster and costs less.

105.9.1.2.3 Kunecatechins.

Kunecatechins [Veregen] is made by extraction from the leaves of *Camellia sinensis* (green tea). The primary active component in this extract is epigallocatechin, a compound in the catechin family. The extract also contains small amounts of gallic acid and three methylxanthines: caffeine, theophylline, and theobromine. Although the mechanism of action has not been determined, possibilities include antioxidative effects, induction of apoptosis (programmed cell death), and inhibition of telomerase (an enzyme cells use to extend the telomere cap on DNA). Kunecatechins is supplied as a 15% ointment to be applied 3 times daily until all warts clear, or for 16 weeks, whichever comes first. In one trial, treatment for 16 weeks produced complete wart removal in 53.6% of patients, compared with 35.3% in those treated with placebo. Adverse effects, which are common, include erythema (70%), pruritus (69%), burning (67%), pain (56%), erosion or ulceration (49%), edema (45%), induration (35%), and rash (2%). Moderate reactions develop in 37% of patients, and severe reactions develop in 30%. Kunecatechins should not be applied to the vagina, rectum, or open wounds. Patients should avoid sexual contact while the ointment is present.

105.9.2 Common Warts

Common warts—also known as verruca vulgaris—manifest as hard, rough, horny nodules. These benign lesions may appear anywhere on the body, but are most common on the hands and feet. The majority of common warts are caused by just three types of HPV, known as HPV-1, HPV-2, and HPV-3.

Like venereal warts, common warts may be removed by physical procedures and with topical drugs. The physical methods are freezing, electrodesiccation (destruction with an electric current), curettage (surgical removal with a loop-shaped cutting tool), and laser therapy. Pharmacologic agents include podophyllin, podofilox, imiquimod, trichloroacetic acid, and topical fluorouracil.

^{10...} ANTIPERSPIRANTS AND DEODORANTS

Perspiration is produced by two types of sweat glands: *eccrine glands* and *apocrine glands*. The eccrine glands secrete profuse, watery perspiration. The apocrine glands secrete a small volume of fluid rich in organic compounds. The unpleasant odor associated with sweating results from chemical and bacterial degradation of the compounds in apocrine sweat. Eccrine glands contribute to odor by creating a moist environment that favors growth of bacteria. Perspiration odor can be reduced with *antiperspirants* (agents that decrease flow of eccrine sweat) and *deodorants* (antiseptics that suppress growth of skin-dwelling bacteria).

^{105....} Antiperspirants.

The principal compounds employed as antiperspirants are *aluminum chlorohydrate*, *aluminum chloride*, and *buffered aluminum sulfate*. These agents can decrease flow of eccrine sweat by 20% to 50%. Reduced flow appears to result from inhibition of sweat production and from partial occlusion of sweat glands. Topical antiperspirants can cause stinging, burning, itching, and irritation. Dermatitis and ulceration occur rarely.

Severe sweating can be reduced with *botulinum toxin type A* [Botox], the same drug used to decrease facial wrinkles ([Box 104-1](#)). Botulinum toxin inhibits release of acetylcholine from sympathetic neurons that innervate sweat glands, and thereby reduces sweat volume. To treat axillary hyperhidrosis (severe underarm sweating), 10 to 15 intradermal injections (0.1 to 0.2 mL apiece) are made into each armpit. The needle employed is very fine (30 gauge) to minimize discomfort. One set of injections can markedly decrease sweating for 6 or more months.

^{105....} Deodorants.

Deodorants inhibit growth of the surface bacteria that degrade components of apocrine sweat into malodorous products; deodorants do not suppress sweat formation. Agents employed as deodorants include *carbanilide*, *triclocarban*, and *triclosan*. These antiseptics are the active ingredients in deodorant soaps, such as Dial, Lifebuoy, Safeguard, and Zest.

^{10...} DRUGS FOR SEBORRHEIC DERMATITIS AND DANDRUFF

Seborrheic dermatitis is characterized by inflammation and scaling of the scalp and face. Skin of the underarms, chest, and anogenital region may also be affected. Symptoms result from an inflammatory reaction to infection with *Pityrosporum ovale*, a microbe in the yeast family.

Symptoms respond rapidly to topical treatment with *ketoconazole* [Nizoral], a drug with activity against yeast (see [Chapter 91](#)). For treatment of seborrhea, ketoconazole is available in a 2% cream

[Kuric], 2% foam [Extina], 2% gel [Xologel], and 1% and 2% shampoos [Nizoral]. The cream and foam formulations are applied twice daily for 4 weeks. The gel is more convenient, being applied once daily for only 2 weeks. Concurrent use of topical glucocorticoids can accelerate initial responses. Once the yeast infection has been controlled, remission can be maintained by periodic use of a shampoo that contains a yeast-suppressing drug, such as *ketoconazole* (in Nizoral), *pyrithione zinc* (in Head & Shoulders), or *selenium sulfide* (in Selsun Blue and Head & Shoulders Intensive Treatment).

^{10...} DRUGS FOR HAIR LOSS

Two drugs are available to promote hair growth: minoxidil and finasteride. Minoxidil is applied topically; finasteride is taken orally. Neither drug was originally developed for baldness: Minoxidil was developed for hypertension, and finasteride for benign prostatic hyperplasia.

^{105....} Topical Minoxidil

Minoxidil is a direct-acting vasodilator used primarily to treat severe hypertension. The drug's basic pharmacology is discussed in [Chapter 45](#). Consideration here is limited to its use against patterned hair loss in men and women.

Minoxidil for treating baldness is available in three formulations, a 2% solution (generic only), a 5% solution [Rogaine Extra Strength for Men], and a 5% foam [Rogaine Men's Extra Strength]. All formulations are approved for men, but only the 2% solution is approved for women. Nonetheless, all formulations are routinely prescribed for women. All formulations are applied to the scalp twice a day.

The mechanism by which minoxidil promotes hair growth is unknown. One possibility is that minoxidil causes resting hair follicles to enter a state of active growth. Improved cutaneous blood flow secondary to vasodilation does not seem to be involved.

Minoxidil can retard loss of hair and stimulate hair growth. Benefits take several months to develop. Unfortunately, response rates are somewhat disappointing: Only about one-third of patients experience significant restoration of hair to regions of baldness. Hair regrowth is most likely when baldness has developed recently and has been limited to a small area. Responses with the 5% solution are only 50% greater than with the 2% solution. When minoxidil is discontinued, newly gained hair is lost in 3 to 4 months, and the natural progression of hair loss resumes. In some cases, beneficial effects may decline even with uninterrupted treatment.

Topical minoxidil is generally devoid of adverse effects. A few patients have reported pruritus and local allergic responses (eg, rash, swelling, burning sensation). Absorption is low, and hence systemic reactions (eg, hypotension, headache, flushing) are rare.

105.... Finasteride

Finasteride is an oral drug with two indications: androgenic alopecia (male-pattern baldness) and benign prostatic hyperplasia (BPH). For treatment of androgenic alopecia, finasteride is sold in 1-mg tablets under the trade name *Propecia*. For treatment of BPH, the drug is sold in 5-mg tablets under the trade name *Proscar* (see [Chapter 65](#)).

Male-pattern baldness is caused by dihydrotestosterone (DHT), a powerful androgenic hormone formed from testosterone. In balding men, the scalp has high levels of DHT, which act on hair follicles to induce shrinkage. Finasteride promotes hair growth by inhibiting the enzyme that converts testosterone into DHT. A 1-mg dose reduces serum levels of DHT by 65% after 24 hours. In the prostate gland, levels of testosterone *increase* by sixfold (because conversion of testosterone into DHT has been suppressed).

Regrowth of hair with finasteride is very modest. The drug has been evaluated in men 18 to 41 years old. Only 50% grew any hair. Furthermore, even when hair growth did occur, the amount was small: One year of treatment with 1 mg/day increased hair count by only 12% (in a 5.1-cm² circle on the scalp, the average hair count rose by 107 hairs, up from a baseline of 867 hairs). In older men taking 5 mg/day to treat BPH, no hair growth has been reported.

1241

105.12.... FACE TIME WITH BOTOX

Frown ridges got you down? Brow lines make you whine? Don't mind injecting your face with a deadly poison? If you answered "Yes" to these questions, then you may be a candidate for Botox—the hottest thing in cosmetic medicine since the nose job. How hot? In 2001, over 1.6 million Americans underwent Botox treatment, making it the number 1 nonsurgical cosmetic procedure in the United States—and that was *before* the drug was approved for cosmetic use.

Why do people love Botox? Because it makes them look younger. By making facial lines go away. Without surgery. And it's cheaper and less traumatic than a face-lift.

Just what is Botox? Well, Botox is a trade name for *botulinum toxin type A*, a protein produced by the gram-negative bacterium *Clostridium botulinum*. And yes, Botox is the

same powerful toxin that causes botulism, a potentially fatal condition brought on by eating foods contaminated with *C. botulinum*. (In case you're curious: Common signs and symptoms include double vision, dysphagia, generalized weakness, urinary retention, and respiratory impairment—all without any decrease in mentation. Death results from respiratory arrest secondary to paralysis of the muscles of respiration.) You're probably asking, “Can *Botox* do all of that?” Not really. The doses approved for cosmetic use are *much* too small to produce these widespread effects. However, if a *huge* dose is injected inadvertently, botulism can indeed result (see below).

How does Botox work? Botulinum toxin type A is a neurotoxin that acts on cholinergic neurons to block release of acetylcholine. Following injection, the drug is taken up by cholinergic nerve terminals, where it inactivates SNAP-25, a protein critical to the function of acetylcholine-containing vesicles. In the absence of SNAP-25, the vesicles are unable to fuse with the terminal membrane, and hence cannot release their acetylcholine. Restoration of neuronal function requires sprouting of new terminals, a process that can take several months. Botulinum toxin blocks transmission at neuromuscular junctions and at cholinergic synapses of the autonomic nervous system.

What are the cosmetic uses of Botox? On April 15, 2002, the Food and Drug Administration (FDA) approved Botox for reducing frown lines, known formally as “glabellar” lines (because they appear on the glabella—the smooth area located between your eyebrows, directly above your nose). At this time, reduction of frown lines is the only cosmetic use approved by the FDA. Nonetheless, Botox is also used widely to soften lines on the forehead and neck, and to diminish “crow's-feet” (lines that form near the outer corners of our eyes when we squint).

Does botulinum toxin have any other approved uses? Yes. And some precede its cosmetic use by more than a decade. In 1989, the FDA approved Botox for two ocular disorders: strabismus (misaligned eye, aka “lazy eye”) and blepharospasm (involuntary, intermittent forced closure of the eyelid). In 2000, botulinum toxin type B was approved for cervical dystonia, a neurologic disorder characterized by painful, sustained contraction of muscles in the neck. And in 2004, Botox was approved for primary axillary hyperhidrosis (excessive underarm sweating). Unlabeled uses include spasmodic torticollis (clonic twisting of the head), hemifacial spasms (unilateral contraction of facial muscles in any combination), migraine headache (injections are made into the scalp), and overactive bladder syndrome.

How is cosmetic Botox applied? With a needle. In the face. To be precise, to reduce frown lines, Botox is injected directly into the small muscles that produce a frown when they

contract. Five injections are made, each consisting of 4 units of botulinum toxin in 0.1 mL of fluid. Two injections go into each corrugator muscle and one into the procerus muscle. The whole procedure takes just a few minutes. Discomfort can be reduced by pretreatment with a topical anesthetic cream.

What's the time course of Botox effects? Results are neither instantaneous nor permanent. Rather, muscle paralysis develops slowly—over 3 to 10 days—and then fades within 3 to 6 months. Botox injections may be repeated to maintain cosmetic benefits. However, at least 3 months should separate treatments. At this time, there are no data on long-term effects.

Does Botox have side effects? Of course—It's a drug, isn't it? The most common side effects are headache, respiratory infection, and a flu-like syndrome. Treatment may also cause facial pain, swelling, and bruising. Swelling and bruising can be reduced by applying ice to the site, and by avoiding alcohol, vitamin E, and aspirin (and related nonsteroidal anti-inflammatory drugs) for the week preceding treatment. There are no data on side effects with repeated use.

Injection into the wrong site (or diffusion from the right site into surrounding tissues) can weaken muscles that were not intended as targets, thereby causing multiple undesired effects. Ptosis (droopy eyelids) occurs in about 5% of patients, and can persist for 3 to 6 months. Injections in the lower face can result in drooling, an asymmetric smile, drooping mouth, and biting the inside of the cheek. Injections in the neck can make swallowing difficult and can change vocal pitch. All of these problems can be reduced by taking steps to minimize Botox displacement. Accordingly, for at least 4 hours after the injections, patients should avoid lying down, rubbing the injection site, and washing their hair. Of course, it also helps to have Botox administered by a highly trained expert, preferably a dermatologist or plastic surgeon.

Excessive cosmetic doses can cause loss of facial expression. Patients can lose the ability to frown, raise their eyebrows, or squint. This may be fine if you're a professional poker player, but can be a disaster if you're an actor—or just an ordinary person who doesn't want to spend a few months projecting Buddha-like calm (rather than the anger you're really feeling because an incompetent physician froze your face).

Who should *not* use Botox? The drug should be avoided by women who are pregnant or breast-feeding, and by patients who may be allergic to human albumin, a protein in Botox preparations. In addition, Botox should be avoided by people using aminoglycoside antibiotics or any other agent that has neuromuscular blocking properties. The drug should be used with caution in patients with myasthenia gravis and other neuromuscular disorders that can intensify muscle paralysis. Lastly, Botox should be avoided by people over 65.

Why? Because it's unlikely to help: In older people, the major cause of lines and wrinkles is loss of elasticity in the skin—a phenomenon that can't be reversed by neuromuscular blockade.

Over time, some patients develop antibodies against botulinum toxin type A. The only consequence is a reduction in Botox benefits. The risk of antibody production may be increased by using high doses and short dosing intervals. If antibodies do develop, patients may still respond to a product known as Myobloc, which consists of botulinum toxin type B (as opposed to botulinum toxin type A).

How is Botox supplied? The drug is available as a powder in 100-unit vials under the name Botox. Immediately before use, the powder is reconstituted with 2.5 mL of preservative-free normal saline to form a clear, colorless solution. According to the package label, reconstituted botulinum toxin is unstable, and hence should be stored cold and used within 4 hours. However, there are data indicating that, if the drug is diluted in normal saline that contains the preservative benzyl alcohol, it retains its potency for 5 weeks—and causes less pain when injected.

How much does Botox cost? About \$300 to \$500 for each area treated (frown lines, forehead, crow's-feet, etc.). The cost to the physician is about \$500 for a 100-unit vial—enough for five treatments. Although labeling prohibits using the same vial for more than one patient, this regulation is often disregarded, thereby saving money for patient and physician alike.

In the United States, botulinum toxin type A is licensed under two trade names: *Botox* and *Botox Cosmetic*. Botox Cosmetic is approved for treating frown lines, whereas plain Botox is approved for treating strabismus, blepharospasm, cervical dystonia, and hyperhidrosis. However, except for the packaging, both Botox products are identical. As noted above, a third brand-name product—*Myobloc*—which contains botulin toxin type B, is approved only for cervical dystonia.

Patients should never ever allow a physician to inject them with an unlicensed botulin toxin product. Why? Because the result could be catastrophic. In 2004, four people became paralyzed with botulism after receiving cosmetic injections at a clinic in Oakland Park, Florida. Turns out the doc in charge wanted to boost profits. So, instead of using the Botox Cosmetic his patients had paid for, Doctor Greedy used a less expensive, highly concentrated preparation intended for laboratory use only. Which might have been OK, if Dr. G had diluted the toxin properly. Which he hadn't. As a result, the amount of botulinum toxin his patients received was 2857 times the lethal dose. (The vial he used had enough toxin to kill over 14,000 people). Fortunately, all four patients survived, and Dr. G.

was given a fat fine and sent to jail. The moral of the story? Select a doctor who doesn't need the biggest boat in the marina, and, just to be safe, be sure to see the vial your Botox is actually coming from.

Because botulinum toxin is the most powerful poison known, terrorists might use it as a weapon. This disturbing possibility is discussed in [Chapter 109](#).

1241

1242

At the dosage employed to treat baldness (1 mg/day), adverse effects are uncommon. About 4% of men experience reduced libido, erectile dysfunction, impaired ejaculation, and reduced ejaculate volume. Finasteride is a teratogen that can cause genitourinary abnormalities in males exposed to the drug *in utero*. Accordingly, women who are or may become pregnant should not take finasteride, nor should they handle tablets that are crushed or broken.

^{10...} EFLORNITHINE FOR UNWANTED FACIAL HAIR

Eflornithine [Vaniqa] is an old drug with a new indication and new formulation. As discussed in [Chapter 98](#), eflornithine has been available since 1990 for *systemic* therapy of African trypanosomiasis (sleeping sickness). Now, the drug is also available in a 13.9% cream, for use by women to remove facial hair. Topical eflornithine acts on cells in hair follicles to inhibit ornithine decarboxylase, an enzyme required for synthesis of polyamines, which in turn are required for cell division and subsequent hair growth.

In clinical trials, eflornithine cream was moderately effective in some women and had no effect in others. All subjects had beards or mustaches that required removal (by shaving, waxing, tweezing, etc.) at least twice a week. Participants were randomized to receive either (1) eflornithine cream twice a week or (2) the vehicle alone (ie, the cream without eflornithine). What happened? Substantial hair reduction occurred in 40% of treated women in one study and 20% of treated women in another, compared with a 10% response in women receiving the vehicle alone. Among the women who did respond, benefits developed slowly—over 4 to 8 weeks or more—and then faded entirely within 8 weeks of stopping treatment. It should be noted that eflornithine does not remove facial hair entirely. Rather, it retards hair growth, causes hair to be finer and lighter, and decreases (but does not eliminate) the need for shaving and other hair-removal procedures. Because effects are not permanent, continuous treatment is required.

Very little of topical eflornithine gets absorbed: about 1% of each dose reaches the systemic circulation. Absorbed drug is eliminated intact in the urine. No metabolism occurs.

Eflornithine cream is generally well tolerated—although there is some concern about possible fetal harm. The most common reactions are transient stinging, burning, tingling, or rash at the application site. Although eflornithine absorption is minimal, it may still be sufficient to cause fetal

injury. In animal studies, there was no evidence that topical eflornithine is teratogenic or fetotoxic. However, of the 19 pregnancies that occurred during clinical trials, there were four spontaneous abortions and one birth defect (Down's syndrome). Until more is known, avoidance of pregnancy would seem prudent.

Eflornithine is supplied in 30-gm tubes (a 2-month supply). Applications are made twice daily, 8 hours apart. Women should rub the cream in thoroughly and should not wash the treated area for at least 4 hours. Cosmetics and sunscreens can be applied as soon as the cream dries.

^{10...} DRUGS FOR IMPETIGO

Impetigo is the most common bacterial infection of the skin. The usual pathogen is *Staphylococcus aureus*. Most cases are seen in children 2 to 5 years old, although all age groups are susceptible. Impetigo is highly contagious and usually spread by person-to-person contact. Fortunately, the infection is superficial, and usually self-limited.

Impetigo has two forms: bullous and nonbullous. Bullous impetigo is caused by a toxin from *Staph. aureus*, and manifests as rapidly spreading papules that may evolve into large, thin-walled vesicles. The usual location is a warm, moist area of the skin. Nonbullous impetigo, also known as crusted impetigo, is caused by *Staph. aureus* and/or *Streptococcus pyogenes*. This infection typically manifests as a single small macule or papule that evolves into a vesicle that oozes a yellow-brown exudate, which then dries into a honey-colored crust. The usual location is skin of the hands, feet, and legs. The majority (70%) of impetigo cases are nonbullous.

Impetigo is treated with antibiotics. Mild to moderate infection can be treated with topical agents. More serious infection is treated with oral agents. Dosages for representative antibiotics are summarized in [Table 104-5](#).

^{105....} Topical Antibiotics

^{105.14....} Mupirocin.

Mupirocin [Bactroban, Bactroban Nasal] is a topical antibiotic with two approved uses: (1) treatment of impetigo caused by susceptible strains of *Staph. aureus*, *Strep. pyogenes*, and beta-hemolytic streptococcus, and (2) eliminating nasal colonization by methicillin-resistant *Staph. aureus* (MRSA). Mupirocin is structurally unrelated to other antibiotics and has a unique mechanism of action: it blocks synthesis of isoleucyl transfer RNA, and thereby inhibits bacterial protein synthesis. At concentrations achieved with topical application, the drug is bactericidal. Mupirocin is active against many gram-positive bacteria and some gram-negative bacteria. Activity is especially good against *Strep. pyogenes* and *Staph. aureus*, including

1242

1243

MRSA. Mupirocin is formulated as a 2% cream and a 2% ointment. For treatment of impetigo, application is done 3 times a day for 3 to 10 days. To eradicate MRSA from the nose, application is done twice daily for 5 days. When mupirocin is applied to the skin, the principal adverse effect is local irritation. Intranasal application can produce headache (9%), rhinitis (6%), upper respiratory congestion (5%), and pharyngitis (4%).

TABLE 104-5 Some Antibiotics for Impetigo

Generic Name	Trade Name	Formulation	Dosage	
			Pediatric	Adult
Topical				
Mupirocin	Bactroban	Ointment, cream	Apply 3 times a day for 3–10 days	Apply 3 times a day for 3–10 days
Retapamulin	Altabax	Ointment	Apply 2 times a day for 5 days	Apply 2 times a day for 5 days
Oral				
Cephalexin	Keflex	Capsules, suspension	3 mg/kg 4 times a day	250 mg 4 times a day
Dicloxacillin		Capsules	6.25 mg/kg 4 times a day	250 mg 4 times a day
Clindamycin	Cleocin	Capsules, suspension	10–20 mg/kg/day in 3 divided doses	300–450 mg 3 times a day
Amoxicillin/clavulanate	Augmentin	Tablets (immediate release, extended release, chewable), suspension	12.5 mg amoxicillin twice daily	875 mg amoxicillin/125 mg clavulanate twice daily

105.14.... Retapamulin.

Retapamulin [Altabax], approved in 2007, is the first representative of a new class of antibiotics, the *pleuromutalins*. Like the macrolides and certain other antibiotics, retapamulin inhibits bacterial protein synthesis by binding with the 50S subunit of bacterial ribosomes. The result is suppression of bacterial growth. *In vitro*, retapamulin inhibits growth of *Strep. pyogenes* and *Staph. aureus*, including MRSA. In addition, the drug is active against *Strep. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, and most anaerobes, including *P.*

acnes. Retapamulin is formulated as a 1% cream and has only one approved use: topical therapy of impetigo caused by methicillin-susceptible strains of *Staph. aureus* or *Strep. pyogenes*. (Even though the drug is active *in vitro* against MRSA, it isn't approved for treating MRSA infections.) Application is done twice daily for 5 days. Adverse effects are limited to local irritation, which develops in 2% of patients. How retapamulin compares with mupirocin for treatment of impetigo has not been established. Unlike mupirocin, retapamulin is not intended for intranasal application.

105.... Oral Antibiotics

Oral antibiotics are indicated when the patient has multiple lesions and when topical therapy has failed. Drugs active against *Staph. aureus* or *Strep. pyogenes* are employed. Among these are cephalexin [Keflex], clindamycin [Cleocin], dicloxacillin (generic only), and amoxicillin/clavulanate [Augmentin]. Dosages are presented in [Table 104-5](#).

10... LOCAL ANESTHETICS

Local anesthetics (eg, benzocaine, lidocaine, pramoxine) can be applied topically to relieve pain and itching associated with various skin disorders, including sunburn, plant poisoning, fungal infection, diaper rash, and eczema. Selection of a topical anesthetic is based on duration of action, desired vehicle (cream, ointment, solution, gel), and prior history of hypersensitivity reactions. The pharmacology of the local anesthetics is discussed in [Chapter 26](#). Agents available for application to the skin are listed in [Table 26-2](#).

105.... KEY POINTS

- Topical glucocorticoids are employed to relieve inflammation and itching associated with a variety of dermatologic disorders.
- Preparations of topical glucocorticoids are classified into four potency groups: low, medium, high, and super-high.
- Prolonged use of topical glucocorticoids can cause atrophy of the dermis and epidermis.
- Topical glucocorticoids can be absorbed in amounts sufficient to cause systemic toxicity. Principal concerns are growth retardation and adrenal suppression.
- Keratolytic agents—salicylic acid, sulfur, and benzoyl peroxide—promote shedding of the horny layer of the skin.

- Topical antibiotics—benzoyl peroxide, clindamycin, and erythromycin—help clear mild to moderate acne by suppressing growth of *P. acnes*.
- Topical retinoids—tretinoin, adapalene, and tazarotene—help clear mild to moderate acne by normalizing hyper-proliferation of epithelial cells in hair follicles.
- Oral antibiotics, including doxycycline and minocycline, are reserved for moderate to severe acne. Benefits derive from suppressing growth of *P. acnes* and from antiinflammatory actions.
- Isotretinoin is an oral drug reserved for severe acne.
- Isotretinoin causes multiple adverse effects, including nosebleeds; inflammation of the lips and eyes; and pain, tenderness, or stiffness in muscles, bones, and joints.
- Isotretinoin is highly teratogenic. Accordingly, all parties involved with the drug—prescribers, patients, pharmacists, and wholesalers—must participate in iPLEDGE, a risk management program designed to ensure that isotretinoin is not used during pregnancy.
- Excessive sun exposure can cause sunburn, premature aging of the skin, and skin cancer.
- Sunscreens can protect against sunburn and aging of the skin, and some cancers.
- To be most effective, a sunscreen product should offer protection against the full range of UVB and UVA radiation.

¹⁰⁶CHAPTER 105 Drugs for the Ear

In this chapter, we discuss drugs for disorders of the middle ear and external ear. In preparation, we review relevant anatomy of the ear.

^{10...}ANATOMY OF THE EAR

The ear has three major divisions: the external ear, middle ear, and inner ear ([Fig. 105-1](#)). Their primary features are as follows:

- The *external ear* consists of (1) the auricle or pinna (the cartilaginous flap visible on the side of the head that serves to collect sound waves); and (2) the external auditory canal (EAC), a skin-lined tube that directs sound waves from the auricle to the tympanic membrane (eardrum). The surface of the EAC is coated with cerumen (earwax), a hydrophobic substance that blocks penetration of water and helps protect against bacterial and fungal infection.
- The *middle ear* is the chamber that houses the malleus, incus, and stapes—three tiny bones that transmit sound vibrations from the eardrum to the internal ear. The middle ear is bounded laterally by the tympanic membrane, which walls off the middle ear from the external ear. The eustachian tube (auditory tube) connects the middle ear with the nasopharynx, and thereby allows air pressure within the middle ear to equalize with air pressure in the environment. The mucociliary epithelium that lines the eustachian tube sweeps bacteria out of the middle ear into the nasopharynx.
- The *inner ear* consists of the semicircular canals and the cochlea. The canals provide our sense of balance. The cochlea houses the apparatus of hearing.

^{10...}OTITIS MEDIA AND ITS MANAGEMENT

Otitis media (OM), defined as an inflammation of the middle ear, is the most prevalent disorder of childhood. The condition affects more than 75% of children by the age of 3 years, and about 95% by the age of 12. In the United States, OM is responsible for more than 30 million clinic visits a year.

Otitis media may result from bacterial infection, viral infection, or noninfectious causes. Only bacterial OM responds to antibiotics. Furthermore, most cases resolve spontaneously, making antibiotics largely unnecessary—even when bacteria *are* the cause. Nonetheless, antibiotics have been used routinely. In fact, OM is the most common reason for giving these drugs to kids—at an estimated cost of \$3.5 billion a year.

106.2.1 Acute Otitis Media

106.2.1.1 Characteristics, Pathogenesis, and Microbiology

Acute otitis media (AOM) is defined by *inflammation* and *fluid in the middle ear*. Otalgia (ear pain) is characteristic, often causing the child to tug at the ear or just hold it. Other possible symptoms include fever, vomiting, irritability, impaired hearing, sleeplessness, and otorrhea (discharge from the ear, usually purulent [pus containing]).

AOM may be bacterial, viral, or both. In children with full-blown bacterial AOM, the inner ear is filled with purulent fluid, which can cause the tympanic membrane to bulge outward. If the membrane is perforated, otorrhea results. In children with nonbacterial AOM or with mild bacterial AOM, the tympanic membrane does not bulge. Of the two presentations—bulging or nonbulging eardrum—nonbulging is the more common.

How does AOM develop? As a rule, the process begins with a viral infection of the nasopharynx, which can cause blockage of the eustachian tube, which in turn can cause negative pressure in the middle ear. When the eustachian tube opens, causing pressure equalization, bacteria and viruses can be sucked in. If the mucociliary system is sufficiently impaired, it will be unable to transport these pathogens back to the nasopharynx. Otitis media results when bacteria colonize the fluid of the middle ear and/or when viruses colonize cells of the middle-ear mucosa. As indicated in [Table 105-1](#), bacteria are present in 70% to 90% of fluid samples taken from the middle ear of children with AOM, and viruses are present in nearly 50%. The most common bacterial pathogens are *Streptococcus pneumoniae* (40% to 50%), *Haemophilus influenzae* (20% to 24%), and *Moraxella catarrhalis* (10% to 15%).

106.2.1.2 Diagnosis

To diagnose AOM, three elements must be present: (1) acute onset of signs and symptoms, (2) middle-ear effusion (MEE), and (3) middle-ear inflammation. The patient history will reveal whether onset of signs and symptoms has been both recent and rapid. The presence of MEE is indicated by any of the following: bulging tympanic membrane (the best predictor of MEE), limited mobility of the tympanic membrane, and otorrhea (fluid in the EAC following perforation of the tympanic membrane). Middle-ear inflammation is indicated by either (1) distinct erythema of the tympanic membrane or (2) distinct otalgia (discomfort, clearly referable to the ear, that disrupts normal activity or sleep).

1244

1245

Figure 105-1 Anatomy of the ear. The *purple arrows* indicate flow of the mucociliary system, which can transport bacteria out of the middle ear.

TABLE 105-1 Primary Pathogens Found in Fluid from the Middle Ear of Children with Acute Otitis Media

Pathogen	Children with the Pathogen (%)
<i>Streptococcus pneumoniae</i>	40–50
<i>Haemophilus influenzae</i>	20–25
<i>Moraxella catarrhalis</i>	10–15
No bacteria found	20–30
Respiratory viruses (with or without bacteria)	48

Frequently, the diagnosis of AOM is somewhat uncertain. Why? Because, in many cases, MEE can't be confirmed. When the presence of MEE is questionable, a diagnosis of AOM may be considered, but cannot be deemed certain.

It is important to distinguish between AOM and otitis media with effusion (OME). As discussed below, children with OME have fluid in the middle ear but no signs of local or systemic illness. Prolonged OME is common following resolution of AOM.

106.2.1.3 Standard Treatment

All children with AOM should receive required pain medication (eg, acetaminophen, ibuprofen, codeine), and some should receive antibiotics—*but only when clearly indicated*. Over the past decade, antibiotic prescriptions for AOM have been declining, a very welcome trend. Why is it welcome? Because the vast majority (over 80%) of AOM episodes resolve spontaneously within a week. Hence, if antibiotics are prescribed routinely, most recipients will be taking drugs they don't really need. Not only does this generate unnecessary expense, worse yet, it puts children at needless risk of adverse drug effects and it accelerates the emergence of antibiotic-resistant bacteria.

In 2004, two organizations—the American Academy of Pediatrics and the American Academy of Family Physicians—released new guidelines for treating AOM in children. The guidelines stress the need for an accurate diagnosis, and they recommend basing treatment on three factors: age, illness severity, and the degree of diagnostic certainty.

For some patients, the guidelines include an important option—*observation*—rather than immediate treatment with antibacterial drugs. Observation is defined as management by

symptomatic relief alone for 48 to 72 hours, thereby allowing time for AOM to resolve on its own. If symptoms persist or worsen, antibacterial therapy is then started. As part of this strategy, parents are informed about (1) the high probability of spontaneous AOM resolution,

1245

1246

and (2) the drawbacks of giving antibiotics when they are not needed. Observation is considered appropriate only when follow-up can be ensured. The recommendation for observation is based on studies showing that:

- Most episodes of AOM resolve spontaneously.

TABLE 105-2 Criteria for Choosing Initial Antibacterial Therapy Versus Observation in Children with AOM

Age	Management Recommendation	
	Certain Diagnosis	Uncertain Diagnosis
Less than 6 months	Antibacterial therapy	Antibacterial therapy
6 months to 2 years	Antibacterial therapy	Antibacterial therapy if illness is severe; observation if illness is not severe*
2 years and older	Antibacterial therapy if illness is severe; observation if illness is not severe*	Observation, regardless of symptom severity

* Severe illness = moderate to severe otalgia or fever of 39°C or higher; nonsevere illness = mild otalgia and fever below 39°C in the past 24 hours.

- Immediate antibacterial therapy is only marginally superior to observation at causing AOM resolution, and is no better at relieving pain or distress.
- Parents find the observation approach acceptable.
- Delaying antibacterial therapy does not significantly increase the risk of mastoiditis, which can occur when bacteria invade the mastoid bone.

Criteria for choosing between observation and initial antibacterial therapy are summarized in [Table 105-2](#). The choice is based on patient age, how certain the diagnosis is, and severity of symptoms. As indicated, all children less than 6 months old should receive antibiotics, regardless of diagnostic certainty or symptom severity. Among children 6 months to 2 years old, antibiotics are indicated whenever the diagnosis is certain. If the diagnosis is uncertain, antibiotics are indicated only if symptoms are severe. For children age 2 years and older, antibacterial therapy is indicated only if the diagnosis is certain, and then only if symptoms are severe. In all other cases, observation is the preferred strategy.

When antibacterial drugs *are* indicated, *high-dose amoxicillin* (40 to 45 mg/kg PO twice a day) is the treatment of choice ([Table 105-3](#)). Benefits of amoxicillin are efficacy, safety, low cost, acceptable taste, and narrow microbiologic spectrum. The duration of treatment ranges from 5 to 10 days, depending on patient age and illness severity.

For patients with penicillin allergy, drug selection depends on allergy severity. If the allergy is *not* severe (type II allergy), a cephalosporin may be used (eg, cefdinir, cefuroxime). However, if the allergy is *severe* (type I allergy, causing urticaria or anaphylaxis), cephalosporins must be avoided, owing to concerns of cross-reactivity. In this case, azithromycin and clarithromycin are recommended.

106.2.1.4 Treatment of Antibiotic-Resistant AOM

Antibiotic resistance is indicated by persistence of symptoms (fever; earache; otorrhea; a red, bulging tympanic membrane) for 2 to 3 days despite antibiotic therapy. Major risk factors for developing resistant AOM are

- Attending day care
- Age less than 2 years
- Exposure to antibiotics in the prior 1 to 3 months
- Winter and spring seasons

Over the past 10 to 15 years, the incidence of resistant AOM has greatly increased. Why? Because overuse of antibiotics has favored emergence of resistant pathogens. Resistance among strains of *H. influenzae* and *M. catarrhalis* is limited to beta-lactam antibiotics. The mechanism is production of beta-lactamase, an enzyme that inactivates amoxicillin and certain other beta-lactam antibiotics. In contrast, strains of *S. pneumoniae* are resistant to multiple antibiotics, including erythromycin and trimethoprim/sulfamethoxazole, as well as amoxicillin and other beta-lactam antibiotics. Interestingly, resistance to amoxicillin does not result from beta-lactamase production. Rather, it results from synthesis of altered penicillin-binding proteins (PBPs), whose affinity for amoxicillin is much lower than that of normal PBPs.

How should resistant AOM be treated? The preferred approach is oral therapy with *high-dose amoxicillin/clavulanate*. The clavulanate (clavulanic acid) in the combination inhibits beta-lactamase, and thereby increases activity against resistant *H. influenzae* and *M. catarrhalis*. Using a high dose of amoxicillin increases activity against resistant *S. pneumoniae*. Because the clavulanate in the combination can cause diarrhea, we want to keep its dosage low. This is

best accomplished by using *Augmentin ES-600* (600 mg amoxicillin/42.9 mg clavulanate), a formulation that contains less clavulanate per milligram of amoxicillin than any other amoxicillin/clavulanate product. To treat resistant AOM, the dosage is 45 mg/kg amoxicillin PO twice a day for 7 days. Alternatives to amoxicillin/clavulanate include *parenteral ceftriaxone* (50 mg/kg IM or IV once a day for 3 days) and clindamycin (30 to 40 mg/kg/day in three divided doses). All three regimens are recommended for (1) children with acute AOM that has not responded to standard antibiotic therapy, and (2) initial therapy of AOM in children with risk factors for resistant infection.

1246

TABLE 105-3 Recommended Antibacterial Drugs for Acute Otitis Media

		Recommended Drugs
Patient Group and Illness Severity		
	For Most Patients	For Patients with Penicillin Allergy [*]
Patients Receiving Immediate Antibiotic Therapy		
Nonsevere illness	Amoxicillin, 40–45 mg/kg twice daily	<i>Non-type I allergy:</i> Cefdinir, 14 mg/kg/day in 1 or 2 divided doses <i>or</i> Cefuroxime, 15 mg/kg twice daily <i>or</i> Cefpodoxime, 10 mg/kg once daily <i>Type I allergy:</i> Azithromycin, 10 mg/kg on day 1, then 5 mg/kg on days 2, 3, 4, and 5 <i>or</i> Clarithromycin, 7.5 mg/kg twice daily
Severe illness	Amoxicillin, 45 mg/kg twice daily <i>plus</i> clavulanate, 3.2 mg/kg twice daily [†]	Ceftriaxone, 50 mg/kg IM for 1 or 3 days
Patients with Persistent Symptoms After 48–72 hr of Observation (with No Antibiotic Therapy)		
	Same as for patients receiving immediate antibiotic therapy	
Patients with Persistent Symptoms After 48–72 hr of Antibiotic Therapy (Indicating Drug Resistance)		
Nonsevere illness	Amoxicillin, 45 mg/kg twice daily <i>plus</i> clavulanate, 3.2 mg/kg twice daily [†]	<i>Non-type 1 allergy:</i> Ceftriaxone, 50 mg/kg IM or IV for 3 days <i>Type I allergy:</i> Clindamycin, 30–40 mg/kg/day in 3 divided doses
Severe illness	Ceftriaxone, 50 mg/kg IM for 3 days	Clindamycin, tympanocentesis

* Type I allergy is severe (urticaria or anaphylaxis); type II is less severe.

† This ratio of amoxicillin to clavulanate can be achieved with Augmentin ES-600, a fixed-dose combination containing amoxicillin and clavulanic acid.

106.2.1.5 Prevention

The risk of acquiring AOM can be decreased in several ways. Breast-feeding for at least 6 months postnatally seems to reduce early episodes of AOM. During infancy and early childhood, AOM can be significantly reduced by avoiding child care centers when respiratory infections are prevalent. Measures of unproved benefit include eliminating exposure to tobacco smoke, reducing pacifier use in the second 6 months of life, and avoiding supine bottle feeding. Two additional measures—prevention and treatment of influenza, and vaccination against pneumococcal infection—are discussed below.

106.2.1.5.1 Prevention and Treatment of Influenza.

As noted, influenza and other viral infections of the respiratory tract predispose children to developing bacterial and viral OM. Accordingly, measures that reduce influenza can reduce OM risk. Two methods are available: (1) vaccination against influenza and (2) treatment of active influenza infection. In one study, day care attendees over the age of 2 years were vaccinated against influenza. The result was a 36% reduction in diagnosed cases of AOM during the 6-week interval when influenza virus was circulating in the community. However, in a study of younger children (ages 6 months to 2 years), influenza vaccination failed to reduce AOM occurrence. In a study involving children with active influenza, treatment with oseltamivir (an antiviral drug) decreased cases of AOM by 40%. Although both approaches—immunization and treatment—can be helpful during the flu season, they do nothing to alter AOM risk the rest of the year.

106.2.1.5.2 *Vaccination Against Streptococcus pneumoniae.*

Vaccination with *pneumococcal conjugate vaccine* (PCV) [Prevnar] can slightly reduce the risk of AOM. Although the vaccine is highly active against the strains of *S. pneumoniae* that cause pneumonia and meningitis, it is only moderately active against the strains that cause AOM. In a study involving 37,868 children in Northern California, the benefits of PCV immunization were significant but modest: office visits for AOM were reduced by 7.8%, and the need for tympanostomy tubes was reduced by 24%.

106.2.2 Recurrent Otitis Media

Recurrent AOM can be defined as AOM that occurs 3 or more times within 6 months, or 4 or more times within 12 months. Four management strategies are available: (1) short-term

antibacterial therapy, (2) prophylactic antibacterial therapy, (3) prevention and treatment of influenza, and (4) placement of a tympanostomy tube.

106.2.2.1 Short-Term Antibacterial Therapy.

There is disagreement regarding antibacterial therapy. Some authorities would prescribe antibiotics for each recurrent episode, regardless of presentation. Others would reserve antibiotics for episodes in which symptoms are severe. In both cases, high-dose amoxicillin is the treatment of choice. If resistance is suspected, amoxicillin/clavulanate can be used.

106.2.2.2 Prophylactic Antibacterial Therapy.

Antibacterial prophylaxis is *not* generally recommended. An analysis of several studies indicates that, for each year of prophylaxis (with *sulfisoxazole*, *trimethoprim/sulfamethoxazole*, or *amoxicillin*), only 1.3 episodes of AOM would be prevented. This small benefit is largely outweighed by the risk of promoting resistance. If prophylaxis is elected, it should be conducted only during the head-cold season. The preferred drug for prophylaxis is amoxicillin. Why? Because, compared with sulfonamides, amoxicillin is more active against multidrug-resistant strains of *S. pneumoniae*.

1247

1248

106.2.2.3 Prevention and Treatment of Influenza.

As discussed above, we can reduce OM occurrence by vaccinating against the influenza virus and by treating active influenza infection. Unfortunately, benefits are seen only during the flu season.

106.2.2.4 Tympanostomy Tubes.

A tympanostomy tube is a small tube that is placed into an incision in the eardrum, thereby permitting drainage and aeration of the middle ear. Tube insertion is performed under general anesthesia and costs about \$3000. In children with recurrent AOM, the procedure can significantly reduce AOM episodes. Complications of the procedure include obstruction of the tube, secondary infection with otorrhea, and premature tube extrusion.

106.2.3 Otitis Media with Effusion

Otitis media with effusion is seen in many children following an episode of AOM. The condition is characterized by fluid in the middle ear but without evidence of local or systemic illness. OME may cause mild hearing loss, but not pain. The condition can persist for weeks to months after AOM has resolved. Antibiotics have minimal effect on OME and should not be used.

^{10...} OTITIS EXTERNA AND ITS MANAGEMENT

Otitis externa (OE) is an inflammation of the external auditory canal. The usual cause is bacterial infection, which may be limited to the EAC, or may spread to adjacent tissues. Most cases of OE respond to topical drugs.

^{106.3.1} Acute Otitis Externa

^{106.3.1.1} Characteristics, Pathogenesis, and Microbiology

Acute OE, also known as “swimmer's ear,” is a bacterial infection of the EAC. The most common pathogens are *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Other pathogens include *Staphylococcus epidermidis* and *Microbacterium otitidis*. Patients who have acute OE present with rapid-onset ear pain associated with pruritus, impaired hearing, purulent discharge, and pronounced tenderness of the auricle upon manipulation.

Susceptibility to acute OE is precipitated primarily by two factors: abrasion and excessive moisture. Both facilitate bacterial colonization. Abrasion of the epithelium creates a site for bacterial entry. Most often, abrasion results from cleaning the EAC with a cotton-tipped swab or some other foreign object (finger, pencil, toothpick, etc.). Abrasion can also be caused by hearing aids and earplugs. Moisture can wash away the protective layer of cerumen. As a result, keratin debris in the EAC is able to absorb water, thereby creating a nourishing medium for bacterial growth. Moisture in the EAC may come from swimming, perspiration, and even high humidity.

^{106.3.1.2} Treatment

Acute OE usually responds well to simple treatment. The goal is to eradicate the pathogen and reduce pain. For most patients, cleaning and use of topical antimicrobials will suffice. If the infection is extensive, oral antibiotics may be needed as well. To facilitate healing, the ear should be kept as dry as possible. Most infections begin to improve in 3 days, and resolve completely by 10 days.

^{106.3.1.2.1} Topical Medications.

Topical antimicrobials are generally preferred to systemic drugs. There are two reasons why. First, because topical agents achieve very high local concentrations—often 100 to 1000 times the concentration achieved with systemic drugs—antibacterial effects are superior: disease persistence is lower and recurrence is less likely. Second, with topical therapy, systemic side effects are absent.

A variety of topical medications can be used. A 2% *solution of acetic acid* is safe, effective, and cheap. Furthermore, because bactericidal activity results from simply reducing pH, there is no risk of encouraging resistance. A solution of *alcohol plus acetic acid* offers the additional benefit of promoting tissue drying. For many patients, acidification and drying are all that is needed.

If the infection cannot be cleared with acetic acid and alcohol, a topical antibiotic should be employed. In the past, a three-drug combination—*hydrocortisone*, *neomycin*, and *polymyxin B*—was considered standard therapy. The hydrocortisone reduces inflammation and edema; neomycin and polymyxin kill bacterial pathogens. Unfortunately, although this combination is effective and inexpensive, it does have drawbacks. Specifically, the neomycin component is ototoxic, and causes local swelling and erythema in about 15% of patients. Today, *fluoroquinolones* (eg, ciprofloxacin) are preferred. Why? Because these drugs are highly effective, don't cause local reactions, and are not ototoxic. Options include Cipro HC (*ciprofloxacin plus hydrocortisone*), Ciprodex (*ciprofloxacin plus dexamethasone*), and Floxin Otic (*ofloxacin* alone). Principal drawbacks of these preparations are expense and promotion of resistance to all fluoroquinolone antibiotics.

Applying ear drops correctly can improve outcomes and reduce drug-related discomfort. Instillation of cold solutions can cause dizziness, and hence ear drops should be warmed prior to administration. Wiggling the earlobe can facilitate transit of solutions down the EAC. If edema of the EAC is sufficient to impede drug penetration, insertion of a sponge wick can help. Drug solutions are absorbed into the wick, which then delivers them to the epithelium of the entire canal. The wick should be removed every 48 hours to allow cleaning and to determine if further wicking is still needed.

106.3.1.2.2 Oral Medications.

Oral antibacterials are indicated if the infection extends beyond the EAC to involve the pinna. For *adults*, *ciprofloxacin* [Cipro] is a good choice. For *children*, *cephalexin* [Keflex], is preferred. Why? Because, oral ciprofloxacin and other fluoroquinolones can cause tendon rupture in younger patients. Accordingly, these drugs should not be given to patients under the age of 18.

106.3.1.3 Prevention

The best way to prevent bacterial OE is to keep the natural defenses of the EAC healthy. Ear hygiene can be promoted by following these rules:

- Don't put *anything* in the ear, including cotton-tipped swabs, fingers, pencils, paper clips, toothpicks, liquids, or sprays, all of which can remove cerumen and/or damage the epithelium.
- Dry the EAC after swimming and showering. How? By toweling off and promoting water drainage (by tipping the head to each side while pulling the auricle in different directions). 1248
1249
- Don't remove cerumen (earwax).
- Don't use earplugs (except when swimming).

^{106.3.2} Necrotizing Otitis Externa

Necrotizing OE is a rare but potentially fatal complication of acute OE that develops when bacteria in the EAC invade the mastoid or temporal bone. Spread of infection to the skull base can affect cranial nerves, and spread to the dura mater can cause meningitis and possibly lateral sinus thrombosis. The usual pathogen is *P. aeruginosa*. Patients typically pre-sent with progressive severe otic pain, purulent discharge from the ear, and granulation of tissue in the EAC. Necrotizing OE occurs almost exclusively in two groups of high-risk people, specifically, older people with diabetes and anyone who is immunocompromised, especially people with HIV infection. Most cases can be managed by thorough cleansing of the EAC followed by treatment with antipseudomonal drugs; surgery is rarely needed. All patients should receive antipseudomonal ear drops (eg, ofloxacin solution). Patients with mild disease should also receive oral ciprofloxacin. Patients with severe disease should receive IV antipseudomonal therapy (eg, *imipenem/cilastatin* [Primaxin], *meropenem* [Merrem IV], or *ciprofloxacin*). The usual duration of IV therapy is 4 to 6 weeks.

^{106.3.3} Fungal Otitis Externa (Otomycosis)

In about 10% of patients, OE is caused by fungi and not bacteria. The two most common pathogens are *Aspergillus*, which causes 80% to 90% of otomycoses, and *Candida*. Fungal OE typically manifests as intense pruritus and erythema, with or without pain or hearing loss. As a rule, otomycosis can be managed with thorough cleansing and application of acidifying drops (eg, 2% acetic acid solution applied 3 to 4 times a day for 7 days). If these measures are inadequate, the patient can apply a solution that contains an antifungal drug (eg, 1% *clotrimazole* [Lotrimin] twice daily for 7 days). If the infection fails to respond, *oral* antifungal therapy may be needed. Options include *itraconazole* [Sporanox] and *fluconazole* [Diflucan].

106.3.3.1

KEY POINTS

- Otitis media (OM), defined as inflammation of the middle ear, is among the most prevalent disorders of childhood.
- *Acute* otitis media (AOM) is characterized by rapid onset, middle-ear effusion, and middle-ear inflammation.
- AOM may be bacterial, viral, or both.
- Over 80% of AOM cases resolve spontaneously within a week.
- All children with AOM should receive pain medication (eg, acetaminophen, ibuprofen, codeine) as needed.
- Recent clinical guidelines recommend antibacterial therapy for some children, and observation for others. (Observation—for 48 to 72 hours—allows time for AOM to resolve on its own. If it doesn't resolve, then antibacterial therapy is implemented.)
- The decision to treat immediately or to wait is based on three factors: patient age, illness severity, and the degree of diagnostic certainty (see [Table 105-2](#)).
- When antibiotics *are* used for AOM (either immediately or after a period of observation), high-dose amoxicillin is the treatment of choice.
- For children with antibiotic-resistant AOM, high-dose amoxicillin/clavulanate (available as Augmentin ES-600) is the treatment of choice.
- The risk of acquiring AOM can be reduced by vaccination against the influenza virus, treatment of active influenza infection, and, to a lesser degree, vaccination against *Streptococcus pneumoniae* (using the pneumococcal conjugate vaccine [Prevnar]).
- Otitis media with effusion (OME) is characterized by fluid in the middle ear but without evidence of local or systemic illness. The condition may cause mild hearing loss, but not pain.
- OME is seen in many children following an episode of AOM, and may persist for weeks to months.
- Antibiotics have minimal effect on OME and should not be used.
- Otitis externa (OE) is an inflammation of the external auditory canal (EAC).

- Acute OE, also known as “swimmer's ear,” is a bacterial infection of the EAC.
- In most cases, acute OE can be treated by cleaning and use of ear drops, which may contain 2% acetic acid (to kill bacteria), alcohol (to promote drying), hydrocortisone (to reduce inflammation and edema), or an antibacterial drug (ciprofloxacin and certain other fluoroquinolones are preferred).
- If acute OE progresses to the pinna, oral antibiotics should be used. Ciprofloxacin is a good choice for adults; cephalexin is a good choice for children.
- Necrotizing OE is a rare but potentially fatal complication of acute OE that develops when bacteria in the EAC invade the mastoid or temporal bone. The usual pathogen is *Pseudomonas aeruginosa*.
- Necrotizing OE can be managed by thorough cleansing and use of antipseudomonal drugs. All patients should receive antipseudomonal ear drops (eg, ofloxacin solution). Patients with mild disease should receive oral ciprofloxacin. Patients with severe disease should receive IV therapy (eg, imipenem/cilastatin [Primaxin]).
- In about 10% of patients with OE, the infection is due to fungi and not bacteria. The most common fungal pathogen is *Aspergillus*.
- Fungal OE (otomycosis) can usually be managed by thorough cleansing and application of acidifying drops (eg, 2% acetic acid solution). If needed, a topical antifungal drug (eg, 1% clotrimazole) can be used. Unresponsive infections can be treated with an oral antifungal drug (eg, itraconazole, fluconazole).

¹⁰⁷CHAPTER 106 Miscellaneous Noteworthy Drugs**^{10...}DRUGS FOR PULMONARY ARTERIAL HYPERTENSION**

Pulmonary arterial hypertension (PAH) is a rare, progressive, and potentially fatal disease of the small pulmonary arteries. The condition is defined by a sustained elevation of pulmonary arterial pressure of more than 25 mm Hg at rest or more than 30 mm Hg during exercise, with a mean pulmonary capillary wedge pressure and left ventricular end-diastolic pressure of less than 15 mm Hg. The primary vascular changes in PAH are vasoconstriction, proliferation of smooth muscle cells and endothelial cells, and pulmonary thrombosis. Cell proliferation and vascular remodeling lead to a progressive increase in pulmonary vascular resistance. The ultimate result is right ventricular failure and death. Although the pathogenesis of PAH is not fully understood, a hormone known as endothelin-1 may play a critical role (see below).

Traditional treatment consists of three drugs: warfarin, a diuretic, and a calcium channel blocker. Warfarin prevents thrombosis. Diuretics reduce fluid retention, and thereby reduce cardiac preload, which in turn reduces symptoms of right-heart failure. Calcium channel blockers dilate constricted pulmonary arteries, and can thereby reduce pulmonary hypertension. However, only 20% of patients respond to calcium channel blockers, hence use of these drugs is limited to this small group.

For many patients, PAH becomes progressively worse despite drug therapy, and hence surgical intervention may be required. Options include single-lung, double-lung, and heart-lung transplantation. These surgeries are high risk, with a mortality rate of 16% to 29%. Five-year survival is 40% to 45%.

Over the last decade, six new drugs for PAH have been approved: epoprostenol, treprostinil, iloprost, bosentan, ambrisentan, and sildenafil. All six promote pulmonary vasodilation. In addition, they may delay or reverse pulmonary vascular remodeling. Also, all six are very expensive ([Table 106-1](#)). Discussion below is limited to these newer drugs.

^{107.1.1}Prostacyclin Analogs

Three derivatives of prostacyclin are approved for PAH: epoprostenol, treprostinil, and iloprost. All three mimic the actions of endogenous prostacyclin, a compound that promotes vascular relaxation, suppresses growth of vascular smooth muscle cells, and inhibits platelet aggregation. Like prostacyclin itself, the analogs bind with cell-membrane receptors and thereby stimulate synthesis of cyclic AMP, an intracellular second messenger that mediates prostacyclin effects. In

patients with PAH, the prostacyclin analogs decrease pulmonary arterial pressure, lower pulmonary arterial resistance, increase exercise tolerance, and improve short-term survival.

107.1.1.1 Epoprostenol

Epoprostenol [Flolan], approved in 1995, was the first prostacyclin available for PAH. Administration is complex and inconvenient, and adverse effects are common. The drug has a very short half-life (less than 6 minutes) and is unstable at room temperature. As a result, it must be given by continuous IV infusion, using a portable pump that can keep the drug cold. Administration is done through a central venous catheter. The infusion rate is low initially, and then gradually increased to a typical maintenance rate of 20 to 40 ng/kg/min. The most common side effects are flushing (58%), headache (49%), and nausea and vomiting (32%). These responses are dose dependent and generally mild. Of greater concern, patients are at risk of catheter-related sepsis. Also, if the pump fails or the catheter becomes dislodged, the resulting interruption of drug delivery can be life threatening.

107.1.1.2 Treprostinil

Treprostinil [Remodulin], approved for PAH in 2002, differs from epoprostenol in three important ways: treprostinil is heat stable, has a longer half-life (4 hours vs. 6 minutes), and can be infused subQ as well as IV. Because treprostinil is heat stable, it doesn't require cooling. Because it has a longer half-life, maintaining a precise infusion rate is less critical. And because the infusion can be done subQ, the risk of sepsis associated with a central venous catheter is obviated. However, subQ infusion of treprostinil is not free of problems: local pain occurs in 85% of patients, and other local reactions (eg, erythema, induration, rash) occur in 83% of patients. Local pain is often dose limiting. Other side effects include jaw pain, diarrhea, edema, and nausea.

1250

1251

TABLE 106-1 Drugs for Pulmonary Arterial Hypertension

Drug	Year Approved	Administration	Adverse Effects	Annual Cost [*]
Prostacyclin Analogs				
Epoprostenol [Flolan]	1995	Continuous IV infusion through a central venous catheter	Catheter-related sepsis, headache, flushing, nausea, vomiting	\$33,000
Treprostinil [Remodulin]	2002	Continuous subQ infusion, or continuous	<i>With subQ infusion:</i> Local pain and other local reactions in most patients	\$97,600
		IV infusion through a central venous catheter	<i>With IV infusion:</i> Catheter-related sepsis	
Iloprost [Ventavis]	2004	Inhalation, 6–9 times a day	Hypotension and fainting, cough, headache, flushing	\$92,000
Endothelin-1 Receptor Blockers				
Bosentan [Tracleer]	2001	Oral, twice a day	Hepatotoxicity, major birth defects, anemia	\$56,000
Ambrisentan [Letairis]	2007	Oral, once a day	Hepatotoxicity, major birth defects, anemia	\$57,000
Phosphodiesterase Type 5 Inhibitor				
Sildenafil [Revatio] [†]	2005 [†]	Oral, 3 times a day	Headache, flushing, dyspepsia	\$12,800

* Payment assistance is available from the manufacturers.

† Sildenafil is also sold as Viagra for treating erectile dysfunction (ED). Approval for ED was granted in 1998.

107.1.1.3 Iloprost

Iloprost [Ventavis], approved for PAH in 2004, is the first prostacyclin that does not require continuous infusion. Instead, the drug is administered by oral inhalation. The usual dosage is 5 mcg inhaled 6 to 9 times a day, using either the *Prodose AAD* system or the *I-neb AAD* system. The most common side effects are cough (39%), headache (30%), flushing (27%), and spasm of the jaw muscles (12%). More importantly, about 11% of patients are at risk of fainting owing to hypotension, which can occur secondary to peripheral vasodilation. To reduce risk, iloprost should be avoided in patients with systolic blood pressure below 85 mm Hg.

107.1.2 Endothelin-1 Receptor Antagonists

Endothelin-1 (ET-1) is a small peptide hormone that promotes vasoconstriction and proliferation of endothelial cells. In patients with PAH, the level of ET-1 in the pulmonary vasculature is elevated as much as 10-fold. Furthermore, the degree of ET-1 elevation corresponds with the degree of PAH severity. Endothelin-1 acts through two types of receptors, known as endothelin type A (ET_A) receptors and endothelin type B (ET_B) receptors. Activation of ET_A receptors causes vasoconstriction and cell proliferation, whereas activation of ET_B receptors causes vasodilation.

Endothelin-1 receptor antagonists (ERAs) can reduce the adverse impact of ET-1 on lung function. In the United States, two ERAs are available: *bosentan* [Tracleer] and *ambrisentan* [Letairis]. A third ERA—*sitaxsentan* [Thelin]—is available in Canada. In patients with PAH, these drugs can improve exercise tolerance and delay symptom progression. Unfortunately, the drugs can also cause serious adverse effects, especially liver injury and fetal malformation.

107.1.2.1 Bosentan

107.1.2.1.1 Actions and Use.

Bosentan [Tracleer], approved in 2001, is a nonspecific ERA that blocks ET_A receptors *and* ET_B receptors. In patients with PAH, the drug improves exercise tolerance and slows symptom progression. Presumably, benefits derive from blocking ET_A receptors rather than ET_B receptors. As noted above, ET_A receptors promote vasoconstriction and cell proliferation, and hence blocking these receptors should reduce pulmonary vascular resistance and may have a favorable impact on vascular remodeling. Blockade of ET_B receptors may be counterproductive, in that the result could be an *increase* in vascular resistance.

107.1.2.1.2 Pharmacokinetics.

Bosentan is an oral drug with 50% bioavailability, both in the presence and absence of food. Plasma levels peak 3 to 4 hours after dosing. Protein binding in blood is high (over 98%). Bosentan undergoes metabolism in the liver, primarily by the cytochrome P450 isozymes CYP2C9 and CYP3A4, followed by excretion in the bile. The drug's half-life is approximately 5 hours.

107.1.2.1.3 Adverse Effects.

The most serious adverse effects are liver injury and teratogenesis. Bosentan can also cause headache, flushing, peripheral edema, nasal congestion, and anemia.

107.1.2.1.3.1 Hepatotoxicity.

Liver injury is common. In 11% of patients, serum levels of liver aminotransferases exceed 3 times the upper limit of normal (ULN). Liver enzymes should be measured at baseline and monthly thereafter. If levels exceed 3 times the ULN at baseline, bosentan should not be used. If levels rise during treatment, and are accompanied by clinical symptoms (eg, nausea, vomiting, fever, jaundice, fatigue), bosentan should be discontinued. Fortunately, all cases of liver injury to date have been reversible; there have been no reports of permanent liver injury or liver failure.

107.1.2.1.3.2 Fetal Injury.

Bosentan is classified in *Food and Drug Administration (FDA) Pregnancy Risk Category X*, and hence must not be used during pregnancy. In rats, the drug caused dose-dependent malformations of the head, mouth, face, and major blood vessels. Accordingly, pregnancy must be ruled out before initiating treatment, and sexually active women must use reliable contraception. Hormonal contraception may be unreliable, and hence should not be the sole form of contraception employed.

107.1.2.1.3.3 Anemia.

Bosentan can reduce hemoglobin levels and the hematocrit. These hematologic changes usually develop during the first weeks of treatment and then stabilize by weeks 4 to 12. Blood tests should be done 1 month and 3 months after starting bosentan, and every 3 months thereafter.

107.1.2.1.4 Drug Interactions.

Bosentan is subject to significant drug interactions. *Inhibitors of CYP2D6 and CYP4A4* have the potential to raise bosentan levels, thereby increasing the risk of toxicity.

Bosentan itself is an inducer of CYP2D6, and hence can accelerate the metabolism of certain other drugs. Important among these are *warfarin* (an anticoagulant that many people with PAH use) and *oral contraceptives*.

Two drugs—*cyclosporine* and *glyburide*—must not be taken with bosentan. Cyclosporine (an immunosuppressant) can greatly increase bosentan levels, and glyburide (a drug for type 2 diabetes) increases the risk of liver injury.

107.1.2.1.5 Preparations, Dosage, and Administration.

Bosentan [Tracleer] is supplied in tablets (62.5 and 125 mg). The dosage is 62.5 mg twice daily for 4 weeks initially, and then increased to 125 mg twice daily for maintenance. In patients with elevated transaminase levels, dosage should be adjusted as follows:

- Above 3 times the ULN but below 5 times the ULN—decrease dosage or interrupt dosing
- Above 5 times the ULN—stop dosing, and don't resume until the level has returned to the baseline value
- Above 8 times the ULN—stop dosing and don't resume

To reduce the risk of liver injury and possible fetal exposure, bosentan must be prescribed through the Tracleer Access Program.

107.1.2.2 Ambrisentan

Ambrisentan [Letairis], approved in 2007, is much like bosentan with regard to actions, indications, and adverse effects. Both drugs block receptors for ET-1; both are taken to improve exercise tolerance and delay symptom progression in PAH; and both can cause liver damage and severe birth defects. The drugs differ primarily in receptor specificity: Whereas bosentan blocks ET_A and ET_B receptors, ambrisentan is selective for ET_A receptors. However, we don't know if this selectivity improves clinical outcome. As with bosentan, patients taking ambrisentan must undergo blood tests of liver enzymes at baseline and monthly thereafter; likewise, pregnancy must be ruled out before starting ambrisentan, and sexually active women must use two reliable forms of contraception. Like bosentan, ambrisentan can cause peripheral edema, headache, flushing, and anemia. In contrast to bosentan, ambrisentan does not reduce levels of warfarin. Ambrisentan is supplied in 5- and 10-mg tablets, which may be taken with or without food. Dosing begins at 5 mg once a day and, if this dosage is tolerated, may be increased to 10 mg once a day. Owing to the risk of birth defects and liver injury, ambrisentan is available only through a restricted distribution program, known as the Letairis Education and Access Program (LEAP).

^{107.1.3} Sildenafil

Sildenafil, sold as *Revatio*, was approved for oral therapy of PAH in 2005. The same drug, sold as *Viagra*, has been available since 1998 for men with erectile dysfunction (ED). The pharmacology of sildenafil and its use in ED are discussed in [Chapter 65](#). Consideration here is limited to its use in PAH.

How does sildenafil work? It causes selective inhibition of phosphodiesterase type 5 (PDE5), the enzyme that inactivates cyclic GMP (cGMP). In arterioles of the lung and other tissues, endogenous nitric oxide triggers synthesis of cGMP, which in turn causes vasodilation. Hence, by inhibiting PDE5, sildenafil can preserve cGMP, and can thereby enhance vasodilation mediated by nitric oxide. In patients with PAH, sildenafil reduces pulmonary arterial pressure and pulmonary vascular resistance. The drug may also suppress proliferation of pulmonary vascular smooth muscle cells.

Sildenafil is generally well tolerated. The most common adverse effects are headache, flushing, and dyspepsia. Transient visual disturbances and priapism (prolonged, painful erection) occur infrequently. Very rarely, men have experienced sudden hearing loss or sight-threatening nonarteritic ischemic optic neuropathy. However, in both cases, a causal relationship has not been established.

Sildenafil can cause mild hypotension when used alone, and significant hypotension when combined with certain drugs. Combined use with alpha-adrenergic blockers can cause symptomatic postural hypotension. Of much greater concern, combined use with nitrates (eg, nitroglycerin, isosorbide dinitrate) can drop blood pressure enough to threaten life. Accordingly, concurrent use of sildenafil and nitrates is contraindicated.

Sildenafil is metabolized by CYP3A4 (the 3A4 isozyme of cytochrome P450). As a result, CYP3A4 inhibitors (eg, ketoconazole, clarithromycin, ritonavir) can raise sildenafil levels, and CYP3A4 inducers (eg, rifampin, phenytoin) can lower its level.

For treatment of PAH, sildenafil is supplied in 20-mg tablets under the name *Revatio*. The recommended dosage is 20 mg 3 times a day, taken with or without food.

^{10...} DROTRECOGIN ALFA (ACTIVATED) FOR SEVERE SEPSIS

^{107.2.1} Introduction to Sepsis and Its Treatment

Sepsis is a life-threatening condition triggered by systemic microbial infection. Symptoms are due primarily to the body's reaction to the infection, and not to the infection itself. Of particular

importance, infection triggers a generalized inflammatory response as well as unregulated activation of the coagulation system. The end result is diffuse endovascular injury and multiorgan dysfunction, often followed by death. The immediate cause of death is progressive hypotension or the failure of at least one organ. Among patients with *severe sepsis*—defined as sepsis plus dysfunction of at least one organ—the death rate is 30%. Among those with *septic shock*—defined as sepsis plus hypotension despite fluid replacement—the death rate is 50%. In the United States, there are about 750,000 cases of sepsis a year, resulting in at least 225,000 deaths. Sepsis is responsible for 9.3% of deaths from all causes, which exceeds mortality from myocardial infarction.

1252

Standard management of severe sepsis consists of the following:

1253

- Aggressive treatment of the underlying infection, using surgical drainage (as appropriate) and IV antimicrobial drugs
- Cardiovascular support, consisting of fluid administration, drug therapy (vasopressors and/or inotropic agents), and possibly transfusions
- Pulmonary therapy, consisting of oxygen and mechanical ventilation
- Renal replacement therapy, if indicated

In addition, patients can benefit from stringent control of blood glucose and, possibly, from glucocorticoids in moderate doses. Unfortunately, despite these interventions, mortality has remained high, indicating a need for better treatments. The introduction of drotrecogin alfa (activated) in 2001, represents a small but significant step toward filling that need.

107.2.2 Drotrecogin Alfa (Activated)

Drotrecogin alfa (activated), sold as *Xigris*, is the first agent approved specifically for sepsis. The drug can reduce mortality in some patients with severe sepsis, but poses a risk of serious bleeding. Drotrecogin alfa (activated) is a derivative of *activated protein C*, an endogenous compound with anticoagulant and anti-inflammatory actions. Drotrecogin alfa is produced by recombinant DNA technology, and then converted to its active form by incubation with thrombin. For the rest of this discussion, the abbreviation *DrotAA* is used in place of *drotrecogin alfa (activated)*, the drug's full generic name.

107.2.2.1 Indications

DrotAA is indicated for IV therapy of severe sepsis in adults who are at high risk of death. For the purpose of patient selection, *severe sepsis* is defined as sepsis associated with acute organ

dysfunction, and *high risk of death* is defined by a score of 25 or higher on an APACHE II evaluation (Acute Physiology and Chronic Health Evaluation II). DrotAA is not indicated for adults who are at lower risk of death (APACHE II score below 25), nor is it indicated for children.

107.2.2.2 Mechanism of Action

DrotAA is an analog of activated protein C, an endogenous compound that helps regulate coagulation and inflammation. How? By promoting fibrinolysis, inhibiting thrombosis, and suppressing inflammation. Of note, in people with severe sepsis, activation of protein C may be impaired. In fact, in the majority of sepsis patients at high risk of death, levels of activated protein C are low. This deficit may contribute to excessive coagulation and inflammation. By mimicking the actions of activated protein C, DrotAA can help suppress coagulation and inflammation, and may thereby help reduce mortality from severe sepsis.

107.2.2.3 Clinical Trials

In clinical trials, DrotAA reduced mortality in adults with severe sepsis and a high risk of death, but not in adults with severe sepsis and a low risk of death, and not in pediatric patients. In the Recombinant Human Activated Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) trial, DrotAA produced a 13% decrease in 28-day mortality, but only in patients with APACHE II scores of 25 or higher. A later study—Administration of Drotrecogin Alfa (Activated) in Early Stage Severe Sepsis (ADDRESS)—confirmed the lack of efficacy in patients with APACHE II scores below 25. A trial in pediatric patients was stopped early because benefits of DrotAA in this group were clearly lacking.

107.2.2.4 Adverse Effect: Bleeding

Bleeding is the most common serious adverse effect. The cause is suppression of coagulation. Patients have experienced intracranial, intra-abdominal, and GI bleeding, as well as bleeds at other sites. Fatal bleeds have occurred. If clinically important bleeding develops, infusion of DrotAA should stop immediately. Once adequate hemostasis has been established, resumption of DrotAA can be considered.

Because of the risk of serious bleeding, the following *contraindications* apply:

- Active internal bleeding
- Hemorrhagic stroke within 3 months
- Intracranial surgery, intraspinal surgery, or severe head trauma within 2 months

- Trauma with an increased risk of life-threatening bleeding
- Use of an epidural catheter
- Intracranial neoplasm or mass lesion
- Evidence of cerebral herniation

DrotAA should be used with *caution* in patients with the following:

- Concurrent use of heparin to treat an active thrombotic or embolic event
- Platelet count below 30 million/mL, even if the platelet count is increased after transfusions
- Prothrombin time/international normalized ratio (INR) greater than 3
- GI bleeding within 6 weeks
- Thrombolytic therapy within 3 days
- Use of warfarin or a glycoprotein IIb/IIIa inhibitor within 7 days
- Use of more than 650 mg aspirin within 7 days
- Ischemic stroke within 3 months
- Intracranial arteriovenous malformation or aneurysm
- Known bleeding disorder
- Chronic severe liver disease
- Any other condition in which bleeding constitutes a significant hazard or would be especially hard to manage owing to its location

107.2.2.5 Drug Interactions

Drug interactions have not been studied in patients with severe sepsis. Nonetheless, because DrotAA promotes bleeding, other drugs that impede hemostasis should be used with caution. In clinical trials, about two-thirds of patients received low doses of unfractionated heparin or low-molecular-weight heparin, with no apparent increase in bleeding events. Whether higher doses of these agents would increase bleeding is not known.

107.2.2.6 Preparations, Dosage, and Administration

Drotrecogin alfa (activated) [Xigris] is supplied as a powder (5 and 20 mg) to be reconstituted for IV use. Patients receive a continuous infusion of 24 mcg/kg/hr for 96 hours. The infusion should be stopped 2 hours before surgery and other invasive procedures, and can be resumed immediately after minor procedures and 12 hours after major surgery, providing hemostasis is adequate.

1253

1255

107.2.2.6.1 BOX 106-1 Special Interest Topic

107.2.2.6.1.1 THALIDOMIDE REDEEMED—AND STRICTLY CONTROLLED

On July 16, 1998, the Food and Drug Administration (FDA) finally approved thalidomide for American use—after denying approval nearly 40 years earlier. Because thalidomide is a powerful teratogen, the FDA requires that prescribers, pharmacists, and patients follow strict safety rules. At this time, the drug has only two approved uses (1) multiple myeloma, an incurable cancer of the bone marrow, and (2) erythema nodosum leprosum (ENL), a painful complication of leprosy. However, thalidomide has shown promise in many other diseases, including inflammatory disorders and several additional types of cancer.

The thalidomide story goes back to the late 1950s, when the drug caused the most notorious tragedy in pharmaceutical history. Thalidomide was developed in Germany for use as a sedative, and was sold over the counter in Europe. Many pregnant women took the drug for morning sickness and insomnia. It was not until 1961 that a terrible truth became known: Thalidomide was causing horrific birth defects. Thousands of children were born with stunted, flipper-like limbs (phocomelia). Others suffered deafness, blindness, facial paralysis, brain damage, kidney malformation, and congenital heart disease. Between 1957 and 1961, thalidomide deformed more than 12,000 babies, and killed untold others *in utero*.

Thanks to Dr. Frances O. Kelsey of the FDA, infants in the United States were spared. It was Dr. Kelsey's job to review the application to market thalidomide here. She had just joined the FDA and this was her first assignment. Being concerned about the drug's safety, Dr. Kelsey turned down the application and demanded more studies. Despite pressure from the manufacturer and from her superiors at the FDA, she continued to hold her ground. The drug's teratogenic potential became known before approval was ever granted. In recognition of her courage and dedication, Dr. Kelsey was given the Distinguished Federal Civilian Service Award by President John F. Kennedy.

Thalidomide appears to have great potential as a therapeutic agent. Responses in cancer have been especially encouraging. In patients with multiple myeloma, thalidomide produced complete remission in 10% of recipients; another 20% or so experienced significant improvement. Furthermore, thalidomide caused fewer adverse effects than traditional anticancer drugs. Early evidence indicates that thalidomide may also help patients with cancer of the prostate, brain, colon, skin, and other organs. Additional conditions for which thalidomide has shown promise include rheumatoid arthritis, systemic lupus erythematosus (SLE), Crohn's disease (an inflammatory bowel disorder), macular degeneration, chronic host-versus-graft disease, and oral aphthous ulcers associated with AIDS.

Several pharmacologic actions may explain therapeutic effects. Of special note are anti-inflammatory and immunomodulating actions, mediated in part by decreased synthesis of tumor necrosis factor- α . In addition, thalidomide suppresses angiogenesis (growth of new blood vessels). This action is thought to underlie benefits in cancer and ENL.

Thalidomide can cause multiple adverse effects. Teratogenesis is most important. A single 100-mg dose can cause birth defects. The incidence is nearly 100% when the drug is taken between days 21 and 36 of gestation. Drowsiness occurs in 36% of patients, and can be intensified by other sedative drugs. Peripheral neuropathy—manifesting as limb weakness, incoordination, and tingling in the fingers and toes—develops frequently, and may be irreversible. Other common effects include constipation, orthostatic hypotension, dizziness, dry mouth, and rash.

Thalidomide is available in capsules (50, 100, and 200 mg) under the trade name *Thalomid*. The wholesale price for a box of 84 capsules is over \$600. Dosing is done in the evening, preferably at bedtime—and at least 1 hour after eating. The dosages employed for ENL, multiple myeloma, and some disorders under investigation are as follows:

- *ENL*—100 to 300 mg/day for at least 2 weeks
- *Multiple myeloma*—200 to 800 mg/day for at least 6 weeks
- *SLE*—50 mg/day
- *Crohn's disease*—50 to 300 mg/day
- *Aphthous ulcers*—50 to 300 mg/day

Because thalidomide is a powerful teratogen, all persons who prescribe, dispense, or use the drug must comply with a strict set of FDA-mandated safeguards, known as the *System for Thalidomide Education and Prescribing Safety*, or *S.T.E.P.S.* The objective of S.T.E.P.S. is to ensure full awareness of teratogenic risk, and to implement measures for risk reduction. The program includes the following important provisions:

- Providers who prescribe thalidomide and pharmacists who dispense it must be registered with the S.T.E.P.S. program.
- Female patients must receive oral and written warning of the risk of birth defects, and must acknowledge their understanding in writing.
- A pregnancy test must be conducted no more than 24 hours before starting therapy. The provider cannot prescribe thalidomide without a written report of a negative test. In addition, pregnancy testing must be done weekly during the first month of treatment, and every 4 weeks thereafter (for women with regular menstrual cycles) or every 2 weeks thereafter (for women with irregular cycles). Thalidomide must be discontinued immediately if pregnancy is detected.
- Female patients must agree in writing to use *two* methods of contraception, a *highly reliable* method (hormonal contraception, tubal ligation, intrauterine device, vasectomy of male partner) and a *reliable* method (cervical cap, diaphragm, latex condom)—beginning 1 month before initiating thalidomide and continuing 1 month after stopping. Contraception is unnecessary for women who (1) have undergone a hysterectomy, (2) are at least 2 years postmenopausal, or (3) choose to abstain from heterosexual intercourse.
- Male patients must receive verbal and written warning of the teratogenic hazards of thalidomide, and must agree to use a latex condom during heterosexual intercourse, even if they've had a successful vasectomy. (We don't know if thalidomide achieves appreciable levels in semen or sperm. Until more is known, precautions for males are prudent.)
- Each box of Thalomid capsules contains a photograph of a thalidomide victim—a baby girl with flipper-like arms and legs. Every time patients reach for a pill, they receive this startling reminder of what thalidomide can do.

^{10...} DRUGS FOR NEONATAL RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) is the primary cause of morbidity and mortality in premature infants. The underlying cause is deficiency of lung surfactant, a complex mixture of phospholipids and apoproteins that lowers surface tension on the alveolar surface. Consequences of surfactant deficiency include alveolar collapse, pulmonary edema, reduced lung compliance, small airway epithelial damage, hypoxia, and ultimately respiratory failure.

Increased production of cortisol during weeks 30 to 32 of gestation initiates production of lung surfactant. However, surfactant production is not fully adequate until weeks 34 to 36. As a result, the earlier the premature infant is delivered, the greater the risk of RDS. Among infants born during weeks 26 to 28, the incidence of RDS is 60% to 80%; by weeks 30 to 32, the incidence drops to 20%.

^{107.3.1} Prenatal and Postnatal Glucocorticoids

When preterm delivery cannot be prevented, injecting the mother with glucocorticoids can accelerate fetal lung maturation, and thereby decrease the incidence and severity of RDS. Glucocorticoids act by stimulating production of fibroblast pneumocyte factor, which in turn stimulates production of surfactant by fetal pneumocytes. Glucocorticoids are effective when used during weeks 24 to 34 of gestation. Beyond week 34, fetal lungs are sufficiently mature that no benefit is gained by giving these drugs. Two drugs are recommended: *dexamethasone* and *betamethasone*. A *single course* consists of either (1) *dexamethasone*, 6 mg IM every 12 hours for four doses, or (2) *betamethasone*, two 12-mg IM doses, injected 24 hours apart. To be effective, the last glucocorticoid dose should be administered at least 24 hours before delivery, but no more than 7 days before. The basic pharmacology of the glucocorticoids is discussed in [Chapters 59](#) and [71](#).

If pregnancy is successfully extended (eg, by giving a uterine relaxant), can repeat courses of glucocorticoids be of benefit? Yes. Giving a repeat course every week until delivery yields better short-term outcomes than giving a single course: With repeat courses, there is a lower incidence of RDS, less need for mechanical respiratory support, and a reduction in serious neonatal morbidity. Furthermore, long-term follow-up studies done to date suggest that repeat courses are safe: Compared with children who received a single prenatal course, those who received repeat prenatal courses showed no deficit in growth, blood pressure, neurocognitive function, or developmental scores, and no increase in neurodevelopmental complications. Nonetheless, since data on long-term outcomes are still limited, it may be prudent to use a reduced glucocorticoid dosage until the long-term safety of repeat courses is better established.

Although the risk/benefit ratio for *prenatal* glucocorticoids is clearly favorable, the risk/benefit ratio for *postnatal* glucocorticoids is not. Yes, postnatal glucocorticoids are effective for prevention and treatment of chronic lung disease in infants. However, there is a high price to pay: Treatment impairs growth, neuromotor development, and cognitive function. In one study, researchers evaluated 8-year-old children who had received dexamethasone when they were infants. Compared with children who had not received dexamethasone, the treated children were 1.5 inches shorter, had smaller heads, and did less well on tests of motor skills, visual-motor integration, and intelligence. In 2002, both the American Academy of Pediatrics and the Canadian Paediatric Society recommended against routine use of systemic dexamethasone for prevention and treatment of chronic lung disease in infants.

^{107.3.2} Lung Surfactant

Lung surfactant, administered by direct intratracheal instillation, is indicated for prevention and treatment (rescue therapy) of RDS. Surfactant therapy lowers the surface tension forces that cause alveolar collapse, and thereby rapidly improves oxygenation and lung compliance and reduces the need for supplemental oxygen and mechanical ventilation. Treatment decreases neonatal mortality by 33%.

In the United States, three preparations of lung surfactant are available: poractant alfa, calfactant, and beractant. Available data are insufficient to recommend any one drug over the others. *Initial* doses for prevention or treatment of RDS are as follows:

- *Poractant alfa* [Curosurf]—2.5 mL/kg
- *Calfactant* [Infasurf]—3 mL/kg
- *Beractant* [Survanta]—4 mL/kg

Because the effects of a single dose are often transient, repeated dosing may be needed. For poractant alfa, repeat doses should be 1.25 mL/kg—half the initial dose. For calfactant and beractant, repeat doses are the same as the initial dose.

Adverse effects result primarily from the administration process. Bradycardia and oxygen desaturation, which occur secondary to vagal stimulation and airway obstruction, are most common. If these occur, it may be necessary to temporarily suspend administration. Other adverse effects include pulmonary hemorrhage, mucus plugging, and endotracheal tube reflux.

^{10...} DRUGS FOR CYSTIC FIBROSIS

Cystic fibrosis (CF) is an inherited disorder that results in damage to the lungs, pancreas, and other organs. About 30,000 U.S. citizens have the disease. Thirty years ago, 50% of children diagnosed with CF died before the age of 5. Today, the mean survival is 35 years. Drugs cannot cure CF, but they can reduce symptoms and retard progression of injury.

^{107.4.1} Pathophysiology of Cystic Fibrosis

The underlying cause of CF is mutation of the gene that codes for a particular type of chloride channel, referred to as the cystic fibrosis transmembrane regulator (CFTR). In cells that have defective CFTRs, the normal transmembrane flow of chloride ions, sodium ions, and water is disrupted. In the lungs, exocrine glands (eg, pancreas), and other structures, disruption of ion and water flux alters secretions.

^{107.4.1.1} Pancreas.

Disruption of chloride transport in the pancreas impairs secretion of bicarbonate and digestive enzymes into the small intestine. The immediate result is maldigestion and malabsorption of fats and other nutrients. Absorption of fat-soluble vitamins, especially vitamins A and E, is reduced secondary to malabsorption of fats. Over time, accumulation of digestive enzymes within pancreatic cells leads to cell destruction. At autopsy, the pancreas appears scarred and fibrotic, which led pathologists to name this illness *fibrocystic disease of the pancreas*—later shortened to cystic fibrosis. Until replacement therapy with pancreatic enzymes became possible, malabsorption of nutrients was the major cause of CF death.

^{107.4.1.2} Lungs.

Today, destruction of lung tissue is the major cause of morbidity and mortality among patients with CF. In the cells that line the airway, defective CFTRs impair secretion of chloride and enhance reabsorption of water and sodium. As a result, mucus becomes thick and viscous, causing plugging of the airway and promoting chronic bacterial colonization. All patients eventually develop active pulmonary infection; the most common pathogens are *Pseudomonas aeruginosa* and *Staphylococcus aureus*. Infection elicits an inflammatory response that is mediated primarily by neutrophils. Accumulation of DNA from dead neutrophils further increases the viscosity of sputum. Over time, chronic bronchitis and associated inflammation cause progressive destruction of lung tissue. In 95% of patients, death from cardiorespiratory failure ultimately ensues.

107.4.1.3 Reproductive Organs.

Among patients with CF, 98% of males and 70% to 80% of females are infertile. In males, the usual cause is obstruction of the vas deferens. In females, the cause appears to be production of thick, sticky cervical mucus, which impedes penetration of sperm.

107.4.2 Drug Therapy

Drugs are used to alleviate symptoms of CF and delay progression of injury to the lungs. Agents employed include pancreatic enzymes, fat-soluble vitamins, antibiotics, dornase alfa, and ibuprofen. Gene therapy is under investigation.

107.4.2.1 Nutritional Drugs

107.4.2.1.1 Pancreatic Enzymes.

These enzymes are given as replacement therapy. All preparations contain lipase, protease, and amylase. The most effective formulations deliver the enzymes in enteric-coated microspheres, which are designed to (1) protect the enzymes from stomach acid and (2) ensure dissolution in the duodenum, the site where the enzymes act. Pancreatic enzymes are discussed in [Chapter 79](#).

107.4.2.1.2 Fat-Soluble Vitamins.

There are four fat-soluble vitamins: A, D, E, and K. Among patients with CF, deficiencies in vitamins A and E are relatively common, whereas deficiency in vitamin K is uncommon and deficiency in vitamin D is rare. Because vitamins are safe and relatively inexpensive, supplementation with all four is done routinely.

107.4.2.2 Pulmonary Drugs

107.4.2.2.1 Antibiotics.

Tobramycin solution for inhalation [TOBI] is the preparation of choice for suppressing chronic infection with *P. aeruginosa*. The dosage is 300 mg every 12 hours in repeating cycles of 28 days on and 28 days off. Inhaled tobramycin improves pulmonary function, reduces the density of *P. aeruginosa* in sputum, and decreases the risk of hospitalization. We don't yet know if this therapy prolongs life. Unlike IV aminoglycosides, inhaled tobramycin does not cause hearing loss, although it can cause tinnitus (ringing in the ears). Because

treatment is prolonged, emergence of resistance is a concern. The basic pharmacology of tobramycin and other aminoglycosides is discussed in [Chapter 86](#).

Acute exacerbations of pulmonary infection can be treated with oral or IV antibiotics. For mild infection, oral agents may suffice. For severe exacerbations, IV antibiotics are required. Options include aminoglycosides (eg, tobramycin, gentamicin), piperacillin/tazobactam, ticarcillin/clavulanate, and imipenem/cilastatin.

107.4.2.2.2 Inhaled Dornase Alfa.

Dornase alfa [Pulmozyme], a purified preparation of recombinant human deoxyribonuclease, decreases the viscosity of sputum in patients with CF. Dornase alfa is administered by inhalation, using an approved nebulizer. Benefits derive from breaking down extracellular DNA that has accumulated in the lungs secondary to death of neutrophils. With daily use, dornase alfa can improve pulmonary function and decrease infection in some patients. The drug is generally well tolerated. Adverse effects include hoarseness, pharyngitis, laryngitis, rash, chest pain, and conjunctivitis. Dosing is begun at 2.5 mg once daily and may be increased to 2.5 mg twice daily if needed. To remain effective, dornase alfa must be administered every day for life. Unfortunately, treatment is expensive. A year's supply of dornase alfa costs over \$12,000. The nebulizer costs another \$2000.

107.4.2.2.3 Oral Ibuprofen.

High-dose ibuprofen can slow progression of pulmonary damage in patients with mild lung disease caused by CF. Benefits derive from suppressing the inflammatory response that underlies destruction of lung tissue. Ibuprofen dosage should be sufficient to produce peak plasma drug levels of 50 to 100 mg/mL. Side effects attributable to ibuprofen include conjunctivitis and epistaxis (nosebleed).

107.4.2.2.4 Inhaled Beta₂-Adrenergic Agonists.

Salmeterol [Serevent Diskus] and other inhaled beta₂ agonists can be used long term to improve lung function. Benefits derive from causing bronchodilation and from improving ciliary function.

10... DRUGS FOR SICKLE CELL ANEMIA

Sickle cell anemia (SCA) is an inherited blood disorder characterized by abnormal hemoglobin, chronic anemia, periodic painful episodes, and reduced life expectancy. The underlying cause is a mutation in the gene that codes for hemoglobin (Hb). People who inherit two copies of the gene

(one from each parent) produce an altered form of Hb, known as HbS. (People with just one copy are carriers, but do not make HbS.) When HbS is fully oxygenated, there is no problem. However, when HbS gives up its oxygen, molecules of HbS can polymerize, forming long, rigid, rod-like chains. As a result, red blood cells (RBCs) assume a sickle (crescent) shape, and hence cannot pass through tiny blood vessels. As more RBCs get stuck, blood flow stops, thereby depriving tissues of required nutrients and oxygen. The result is severe pain, referred to as a vaso-occlusive crisis. Pain location depends on where vessel blockage occurs (eg, hands and feet, joints and extremities, abdomen). The crisis may last a few hours to a few weeks. Some patients have 15 or more painful episodes a year, whereas others may have 1 a year or less. Over time, vaso-occlusive events produce progressive organ damage and premature death. The median age at death is 42 for men and 48 for women. In many cases, death results from pulmonary arterial hypertension. Management of this condition is discussed above.

1256

1257

In addition to vaso-occlusive events, people with SCA experience chronic anemia (shortage of RBCs). Why? Unlike normal RBCs, which persist about 120 days, sickled RBCs die in 10 to 20 days. Because RBC loss is unusually rapid, replacements cannot be made fast enough, and hence a chronic shortage results.

Who is vulnerable to SCA? Worldwide, millions of people have the disease. In the United States, about 72,000 people have SCA. Most are African Americans (about 1 in 700 carry two copies of the sickle cell gene, and 1 in 14 carry one copy). In addition, SCA afflicts between 1 in 1000 and 1 in 1400 Hispanic Americans. The disease is not found among white Americans.

Researchers believe that the sickle cell mutation arose in a region where malaria is endemic. There is evidence that, in people with *one* copy of the gene, malaria is less deadly than in people who do not have the gene. As a result, those who carried the gene were more likely to survive, and hence could pass the advantage on to their children. Of course, in areas like the United States, where malaria rarely occurs, the gene offers no survival advantage—and, when two copies are inherited, the gene becomes a real threat to survival.

Treatment consists of transfusions, analgesics, glucocorticoids, and hydroxyurea. Blood transfusions help correct anemia and reduce painful episodes. Analgesics and glucocorticoids can alleviate pain. Hydroxyurea can reduce the incidence and severity of painful episodes and, perhaps more importantly, it can prolong life.

^{107.5.1} Analgesics and Glucocorticoids

For patients undergoing an acute crisis, analgesics and hydration are the cornerstone of treatment. Unfortunately, most patients generally fail to receive adequate pain relief. If the pain is moderate, a nonopioid analgesic (acetaminophen or a nonsteroidal anti-inflammatory agent) may be

sufficient. However, if pain is severe, intensive therapy with an opioid is required. Parenteral (IV or IM) morphine and meperidine have been employed. Patient-controlled analgesia may be especially effective. The basic pharmacology of the opioids is discussed in [Chapter 28](#).

High doses of intravenous methylprednisolone (a glucocorticoid) can shorten the duration of a sickle cell crisis. The drug should be used together with an opioid, not instead of. Unfortunately, when glucocorticoids are discontinued, rebound pain may occur. The basic pharmacology of the glucocorticoids is discussed in [Chapters 59](#) and [71](#).

107.5.2 Hydroxyurea

Hydroxyurea [Droxia, Hydrea] a drug developed to treat cancer (see [Chapter 101](#)), is now being used against SCA. Treatment can reduce the number of painful events as well as the need for hospitalization and transfusions. Furthermore, it can reduce mortality. Currently, hydroxyurea is approved only for adults.

107.5.2.1 Mechanism of Action.

Hydroxyurea increases production of fetal hemoglobin (HbF), a form of Hb present in infants but not normally present after the sixth month of postnatal life. In patients with SCA, elevation of HbF decreases hemoglobin polymerization, and thereby decreases RBC sickling and prolongs RBC life. Hydroxyurea also reduces adhesion of RBCs to the vascular endothelium. Precisely how the drug elevates HbF has not been established.

107.5.2.2 Clinical Trials.

The first major study with hydroxyurea—the Multicenter Study of Hydroxyurea (MSH) in Sickle Cell Anemia trial—was conducted between 1992 and 1995. In this double-blind, randomized, placebo-controlled trial, hydroxyurea produced a 44% reduction in the incidence of painful episodes, a 58% reduction in hospitalizations, and a 34% reduction in transfusions. On the basis of these results, the FDA approved hydroxyurea for reducing painful episodes in adults with SCA. In 2003, results of the MSH Patients' Follow-up trial were published. This trial, which followed patients from the original MSH trial, evaluated the impact of prolonged therapy (up to 9 years) on mortality. The result? Mortality among patients taking hydroxyurea was 40% lower than among those not taking the drug. Furthermore, reductions in mortality were proportional to the extent of HbF elevation and to reductions in painful episodes. It is important to note that hydroxyurea is more likely to benefit patients with severe SCA than patients with moderate or mild SCA. Accordingly, treatment is strongly recommended for the 30% of patients with severe SCA, and is not recommended for the 20% of patients with mild SCA. Whether the drug should be used by the 50% of patients with moderate SCA is unclear.

107.5.2.3 Adverse Effects.

The principal concern is *myelosuppression*, which can reduce neutrophil, platelet, and reticulocyte counts. However, at the doses employed for SCA, myelosuppression is mild and transient. Nonetheless, frequent monitoring of hematologic status is recommended.

Hydroxyurea can cause *fetal harm*, and hence should be avoided during pregnancy. The drug is classified in FDA Pregnancy Risk Category D.

Among patients receiving hydroxyurea for cancer, a few have developed leukemia. However, it is not clear that hydroxyurea was the cause.

At this time, possible long-term adverse effects are unknown.

107.5.2.4 Hematologic Monitoring.

Hematologic status should be determined every 2 weeks. Acceptable values and values indicating toxicity are as follows:

- *Neutrophils*—acceptable, 2500 cells/mm³; toxic, below 2000 cells/mm³
- *Platelets*—acceptable, 95,000/mm³; toxic, below 80,000/mm³
- *Hemoglobin*—acceptable, 5.3 gm/dL; toxic, below 4.5 gm/dL
- *Reticulocytes*—acceptable, 95,000/mm³ (if Hb is below 9 gm/dL); toxic, below 80,000/mm³ (if Hb is below 9 gm/dL)

107.5.2.5 Preparations, Dosage, and Administration.

For treatment of SCA, hydroxyurea [Droxia, Hydrea] is available in capsules (200, 300, 400, and 500 mg). The initial dosage is 15 mg/kg once a day. If blood counts remain acceptable, dosage may be increased by 5 mg/kg/day every 12 weeks—up to a maximum of 35 mg/kg/day. If blood counts indicate toxicity, treatment should be temporarily interrupted. Recovery usually occurs in 2 weeks, after which treatment can be resumed, but at a reduced dosage.

1257

10... DRUGS FOR HYPERURICEMIA CAUSED BY CANCER CHEMOTHERAPY

1258

Hyperuricemia (elevation of uric acid levels) is a common consequence of cancer chemotherapy. The cause is breakdown of DNA following massive cell death. Two drugs are available for management: rasburicase and allopurinol. Rasburicase, a relatively new drug, accelerates uric acid removal; allopurinol, an old drug, blocks uric acid production.

107.6.1 Rasburicase

107.6.1.1 Action and Use.

Rasburicase [Elitek], produced by recombinant DNA technology, is a form of urate oxidase, an enzyme that converts uric acid into a soluble, inactive product (allantoin). The drug is indicated for management of hyperuricemia in pediatric patients undergoing treatment for leukemias, lymphomas, and solid tumors—diseases in which cell lysis caused by chemotherapy is expected to produce a significant increase in plasma uric acid.

107.6.1.2 Adverse Effects.

In clinical trials, the most common reactions were vomiting (50%), fever (46%), nausea (27%), abdominal pain (20%), constipation (20%), diarrhea (20%), and rash (13%). More serious reactions included neutropenia with fever (4%), respiratory distress (3%), sepsis (3%), and mucositis (2%). The most severe reactions, which occurred in 1% of patients or less, were hemolysis, methemoglobinemia, and severe allergic reactions, including anaphylaxis; if any of these reactions occurs, rasburicase should be discontinued immediately and never used again.

107.6.1.3 Preparations, Dosage, and Administration.

Rasburicase [Elitek] is supplied as a powder (1.5 mg/vial) for reconstitution in the diluent provided. Vigorous agitation should be avoided. The recommended dosage is 0.15 or 0.2 mg/kg, infused over 30 minutes, on 5 consecutive days. Start the first infusion 4 to 24 hours prior to the first dose of chemotherapy.

107.6.2 Allopurinol

Allopurinol [Zyloprim] is used to manage hyperuricemia associated with gout and with cancer chemotherapy. Benefits derive from inhibiting xanthine oxidase, the enzyme needed to convert DNA breakdown products (xanthine and hypoxanthine) into uric acid. Allopurinol is discussed at length in [Chapter 73](#) (Drug Therapy of Gout).

10... GAMMA-HYDROXYBUTYRATE FOR CATAPLEXY IN PATIENTS WITH NARCOLEPSY

107.7.1 History.

Gamma-hydroxybutyrate (GHB) [Xyrem], also known as *sodium oxybate*, is a central nervous system (CNS) depressant with a rapid onset and short duration. The drug was originally

developed as a surgical anesthetic, but was discontinued owing to serious side effects: profound respiratory depression, coma, and death. In the 1990s, GHB gained notoriety as a drug of abuse: It was used at parties to produce euphoria and disinhibition, and it was administered clandestinely to facilitate rape (see [Chapter 39](#), [Box 39-1](#)). As a result, GHB was declared illegal.

107.7.2 Therapeutic Use.

In 2002, GHB became the first and only drug approved by the FDA for treating *cataplexy* in patients with narcolepsy. Narcolepsy itself, which afflicts about 120,000 Americans, is characterized by fragmented sleep, daytime somnolence, and uncontrollable attacks of sleep during waking hours. In addition, about 60% to 70% of patients experience cataplexy (sudden loss of muscle tone), typically triggered by intense emotion, such as anger, fear, grief, or even amusement. A cataplectic attack may last a few seconds to many minutes, and can range in severity from dropping of the jaw or slumping of the head to buckling of the legs or collapse of the entire body. As discussed in [Chapter 36](#), patients take CNS stimulants (eg, methylphenidate [Ritalin], dextroamphetamine [Dexedrine]), to promote daytime wakefulness and reduce sudden sleep attacks. GHB is indicated specifically to reduce attacks of cataplexy. Benefits appear to derive from rebound CNS excitement that occurs when the drug's depressant effects wear off. In addition to reducing cataplexy, GHB can improve the quality of nighttime sleep, and can thereby help reduce daytime sleepiness.

107.7.3 Adverse Effects and Abuse.

In clinical trials, GHB produced confusion, depression, headache, dizziness, sleepwalking, bedwetting, nausea, and vomiting. In two patients, respiratory depression occurred. The risk of respiratory depression is increased by combining GHB with alcohol and other CNS depressants. Because of its sodium content (a 9-gm dose contains 1.6 gm of sodium), GHB may pose a risk to patients with heart failure. Abuse of the drug could cause physical dependence. Because of its abuse history, GHB is regulated as a Schedule III substance.

107.7.4 Availability.

Owing to concerns about adverse effects and abuse, availability of GHB is regulated under a strict and comprehensive risk management program. Provisions include limited distribution, prescriber and patient education, prescriber and patient registries, and detailed patient surveillance. Under the program, GHB can be obtained only through a single centralized pharmacy. Before the pharmacy can dispense GHB, the prescriber must verify that the patient has received instruction on its safe use.

^{107.7.5}Preparations, Dosage, and Administration.

Gamma-hydroxybutyrate [Xyrem] is available in oral solution (500 mg/mL in 180-mL bottles). Patients take two doses each night, one at bedtime and one 2.5 to 4 hours later. At treatment onset, each dose is 2.25 gm (4.5 gm total per night). Dosage can be gradually increased to a maximum of 9 gm total per night. In patients with impaired liver function, the dosage should be halved. Treatment is expensive: at 9 gm per night, the cost is about \$740 per month (\$8880 per year).

^{10...}RILUZOLE FOR AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS; Lou Gehrig's disease) is a neuromuscular disorder characterized by progressive muscle wasting and loss of strength. The underlying cause is degeneration of motor neurons, especially in the outside (lateral) portion of the spinal cord. Why motor neurons degenerate is unknown. Initial symptoms typically include weakness in the hands and legs, muscle cramps, stiffness, and twitching. Over time, the patient becomes weaker and weaker. Eventually, all skeletal muscles, including the muscles of respiration, become paralyzed. Intellectual function, eye movement, bladder function, and sensation are not affected. Most patients die within 3 to 5 years, although some survive for a decade or longer. In the United States, ALS strikes about 5000 people each year. At this time, the disease has no cure.

1258

1259

Riluzole [Rilutek], a glutamate antagonist, is the only drug approved for ALS. In clinical trials, the drug prolonged life or delayed the need for a tracheostomy by 3 to 6 months. However, not only were benefits modest, they were limited to patients whose nerve degeneration began in the *medulla*; riluzole did not help patients whose nerve degeneration began in the *spinal cord*. The reason for this difference is unknown. Riluzole is generally well tolerated. The most common adverse effects are asthenia (decreased strength), GI reactions (nausea, vomiting, diarrhea, abdominal pain), CNS effects (dizziness, vertigo, somnolence), and decreased lung function. Riluzole is available in 50-mg tablets for oral administration. The recommended dosage is 50 mg every 12 hours. Increasing the dosage does not increase benefits, but does increase adverse effects. Riluzole should be taken 1 hour before meals or 2 hours after so as to increase bioavailability.

^{10...}PHOSPHATE BINDERS FOR PATIENTS ON DIALYSIS

Phosphate binders are used to treat hyperphosphatemia, a common complication of end-stage renal disease. Blood phosphate is high during renal failure because glomerular filtration of phosphate is reduced and tubular reabsorption of phosphate is increased. Hyperphosphatemia is a concern because it promotes hyperparathyroidism, which in turn promotes *hypercalcemia*, a risk factor for cardiovascular (CV) calcification and CV morbidity and mortality.

Treatment of hyperphosphatemia consists of three measures: (1) reducing phosphate intake, (2) removing phosphate with hemodialysis, and (3) reducing intestinal absorption of phosphate with a phosphate-binding drug. Reducing phosphate in the diet is problematic in that most dietary phosphate comes from proteins (eg, meats, fish, dairy products, peas, and lentils). Hence, reducing dietary phosphate may result in malnutrition. Accordingly, the ability to manage hyperphosphatemia by reducing phosphate intake is limited.

As indicated in [Table 106-2](#), phosphate-binding drugs fall into two major groups: *calcium-based phosphate binders* (eg, calcium carbonate) and *calcium-free phosphate binders* (eg, sevelamer carbonate). All of these drugs are equally effective at reducing phosphate absorption. And they all pose a risk of adverse GI effects. The principal differences among them relate to (1) *price* (the calcium-based drugs cost about 10 times less than the calcium-free drugs) and (2) the risk of exacerbating *hypercalcemia* (the calcium-based drugs increase hypercalcemia risk, whereas the calcium-free drugs do not). Because of these differences, the prescriber is faced with a dilemma: Do I save the patient money (with a calcium-based binder), but increase the risk of hypercalcemia and associated CV calcification? Or do I reduce the risk of hypercalcemia (with a calcium-free binder), but greatly increase the cost? A reasonable solution to the dilemma might be this: Reserve the expensive, calcium-free binders for patients who already have hypercalcemia and evidence of coronary artery calcification, and prescribe the cheaper, calcium-free binders for patients with normal calcium levels and no coronary calcification.

Of the calcium-free phosphate binders in current use, one drug—sevelamer—deserves comment. Sevelamer is available as two salts: *sevelamer hydrochloride* [Renagel] and *sevelamer carbonate* [Renvela]. Both salts are equally good at reducing absorption of dietary phosphate, and they both share an additional asset: they can bind with bile salts in the intestine, and can thereby decrease the synthesis of cholesterol, a major risk factor for CV morbidity and mortality. Although these salts are very similar, they differ in one important way: Sevelamer hydrochloride can cause *metabolic acidosis*, whereas sevelamer carbonate may not. Metabolic acidosis is a concern because it increases the risk of hyperkalemia, breakdown of proteins, bone dissolution, osteodystrophy, and even death. Since the carbonate component of sevelamer carbonate can act as a buffer, the risk of acidosis with this salt is likely to be lower than with sevelamer hydrochloride. However, there are no data to show that patients fare better with the carbonate salt.

1259

1260

TABLE 106-2 Phosphate Binders for Patients on Renal Dialysis

Drug	Trade Name	Formulation (Including Calcium Content)	Usual Single Dose (Taken 3 Times a Day with Meals)	Calcium Load (mg/day)	Comments
Calcium-Based Phosphate Binders					
Calcium carbonate	Os-Cal 500	Tablets, 1250 mg (500 mg Ca)	1250 mg	1500	Cheap, but can promote hypercalcemia
	Caltrate-600	Tablets, 1500 mg (600 mg Ca)	1500 mg	1800	
Calcium acetate	PhosLo	Tablets, 667 mg (169 mg Ca)	2001–2668 mg	507–676	Cheap, but can promote hypercalcemia
		Gelcaps, 667 mg (169 mg Ca)	2001–2668 mg	507–676	
Calcium-Free Phosphate Binders					
Sevelamer hydrochloride	Renagel	Tablets, 400 mg (0 mg Ca)	800–1600 mg	0	Expensive; lowers cholesterol; does not promote hypercalcemia, but does promote metabolic acidosis
		Tablets, 800 mg (0 mg Ca)	800–1600 mg		
Sevelamer carbonate	Renvela	Tablets, 800 mg (0 mg Ca)	800–1600 mg	0	Same as sevelamer hydrochloride, but may cause less metabolic acidosis
Lanthanum carbonate	Fosrenol	Chewable tablets, 250, 500, 750, and 1000 mg (0 mg Ca)	500–1000 mg	0	Expensive; does not lower cholesterol; does not promote hypercalcemia or metabolic acidosis

107.9.1

KEY POINTS

- Pulmonary arterial hypertension (PAH) is a potentially fatal disease of the small pulmonary arteries.
- The primary vascular changes in PAH are vasoconstriction, proliferation of smooth muscle cells and endothelial cells, and pulmonary thrombosis.

- Prostacyclin analogs (eg, epoprostenol, iloprost) reduce symptoms of PAH by promoting vasodilation, suppressing proliferation of smooth muscle cells, and inhibiting platelet aggregation.
- Epoprostenol is administered by continuous IV infusion through a central venous catheter, and hence is inconvenient as well as dangerous (owing to a risk of catheter-related sepsis).
- Iloprost is administered by oral inhalation, and hence is much more convenient than epoprostenol. However, iloprost can cause significant hypotension.
- Bosentan is an endothelin-1 receptor antagonist indicated for oral therapy of PAH. Benefits derive from reducing pulmonary vascular resistance and altering vascular remodeling.
- Bosentan is hepatotoxic and highly teratogenic.
- Sildenafil is a PDE5 inhibitor used for oral therapy of PAH. Inhibition of PDE5 preserves cGMP in pulmonary arteries, and thereby enhances vasodilation mediated by nitric oxide.
- Sepsis is a life-threatening condition in which systemic infection triggers a generalized inflammatory response and activation of the coagulation system. The end result is diffuse endovascular injury and multiorgan dysfunction, often leading to death.
- Drotrecogin alfa (activated)—abbreviated DrotAA—is the only drug approved specifically for severe sepsis.
- DrotAA is indicated for severe sepsis in adults who are at high risk of death, but not for adults with severe sepsis who are at low risk of death, and not for children.
- DrotAA is a derivative of activated protein C, an endogenous compound with anticoagulant and anti-inflammatory actions.
- In patients with sepsis, DrotAA can suppress coagulation and inflammation, and may thereby decrease mortality.
- Because of its anticoagulant actions, DrotAA can cause potentially fatal bleeding.
- Respiratory distress syndrome (RDS), the primary cause of morbidity and mortality in premature infants, results from a deficiency in lung surfactant.

- When preterm birth is unavoidable, injecting the mother with glucocorticoids can accelerate fetal lung maturation, and can thereby decrease the risk of RDS.
- Lung surfactant—poractant alfa, calfactant, or beractant—is given to preterm infants to prevent or treat RDS.
- Cystic fibrosis (CF) is an inherited disorder that results in damage to the lungs, pancreas, and other organs.
- Inhaled dornase alfa [Pulmozyme] can improve pulmonary function and decrease infection in some patients with CF. The drug decreases the viscosity of sputum by breaking down extracellular DNA that has accumulated secondary to death of neutrophils.
- Inhaled tobramycin [TOBI] is the drug of choice for treating chronic *P. aeruginosa* pulmonary infection in patients with CF.
- High-dose ibuprofen can slow progression of pulmonary damage in CF. Benefits derive from suppressing the inflammatory response that underlies destruction of lung tissue.
- In patients with CF, supplemental pancreatic enzymes promote digestion and absorption of nutrients. All preparations contain lipase, protease, and amylase.
- In patients with sickle cell anemia (SCA), hydroxyurea can reduce the number of painful episodes, hospitalizations, and transfusions, and can prolong life. Benefits derive from increasing production of fetal hemoglobin.
- At high doses, hydroxyurea can cause severe myelosuppression. However, at the doses employed for SCA, myelosuppression is transient and mild.
- Hyperuricemia secondary to cancer chemotherapy can be managed with two drugs: rasburicase (which accelerates uric acid removal) and allopurinol (which blocks uric acid production).
- Gamma-hydroxybutyrate can decrease attacks of cataplexy in patients with narcolepsy, and can also decrease daytime drowsiness (by helping to promote sleep).
- Gamma-hydroxybutyrate has significant abuse potential and can cause serious adverse effects (respiratory depression, coma, death). Accordingly, distribution of the drug is strictly controlled.

- In patients with amyotrophic lateral sclerosis (Lou Gehrig's disease), riluzole [Rilutek] can prolong life or delay the need for a tracheostomy by a few months.
- Phosphate binders are used to treat hyperphosphatemia, a common complication of end-stage renal disease.
- Calcium-based phosphate binders (eg, calcium carbonate) are cheap, but pose a risk of hypercalcemia.
- Calcium-free phosphate binders (eg, sevelamer carbonate) do not promote hypercalcemia, but cost much more than the calcium-based drugs.

¹⁰⁸CHAPTER 107 Dietary Supplements

SUSAN PAULSEN

RICH LEHNE

The Food and Drug Administration (FDA) defines dietary supplements as “vitamins, minerals, herbs and other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites” intended to supplement the diet. Throughout history, preparations made from or containing these agents have been employed as remedies.

Dietary supplements are the most common form of *complementary and alternative medicine* (CAM), which can be defined as treatment practices that are not widely accepted or practiced by mainstream clinicians in a given culture. CAM encompasses a large and diverse group of theories and practices. Among these are prayer, homeopathy, massage, mind-body techniques, therapeutic touch, acupuncture, and treatment with vitamins, minerals, nonvitamin/nonmineral products (eg, herbal products), and other natural remedies.

In the United States, use of CAM is widespread. According to the 2007 National Health Interview Survey (NHIS), conducted by the National Center for Health Statistics, 4 out of 10 Americans used some form of CAM in the previous year. The forms of CAM used most often were nonvitamin/nonmineral natural products (17.7%) and deep breathing exercises (12.7%). Usage was highest among American Indian and Alaskan Native adults (50.3%), lower among white adults (43.1%) and Asian adults (39.9%), and lowest among black adults (25.5%).

The popularity of herbal medicine may be explained by several factors ([Table 107-1](#)). Some people like the sense of empowerment that comes from self-diagnosis and selfprescribing. Others may turn to herbal therapy out of anger or frustration with their healthcare providers. Still others may distrust conventional medicine or may feel it has failed them. In addition, herbal products may also be a way to save money: Since these products are available without prescription, they can be purchased without the cost of visiting a prescriber. In fact, according to the NHIS, there is a clear relationship between concern about the costs of conventional care and the likelihood of turning to CAM. However, perhaps the strongest force driving the demand for nutritional supplements is aggressive marketing.

Much of our information on *botanicals* has been amassed by the German Commission E, an expert panel composed of physicians, pharmacists, pharmacologists, and biostatisticians. The commission was established by the German Federal Health Agency (equivalent to our FDA) to review and analyze the world literature on plant-based products. Commission E monographs contain information

on the chemistry, pharmacology, toxicology, and traditional uses of medicinal herbs, as well as data on clinical trials, epidemiologic studies, and patient case records.

Despite the work of Commission E, our understanding of CAM is far from complete. To advance our knowledge, the National Institutes of Health created the National Center for Complimentary and Alternative Medicine (NCCAM) in the late 1990s. The NCCAM is charged with promoting and funding basic research and clinical trials designed to address open questions on the safety and efficacy of CAM.

TABLE 107-1 Why People Use Medicinal Herbs

- Perception that herbs are safer and “healthier” than conventional drugs
- Sense of control over one's care
- Emotional comfort from taking action
- Cultural influence
- Limited access to professional care
- Lack of health insurance
- Convenience
- Media hype and aggressive marketing
- Recommendation from family and friends

10... REGULATION OF DIETARY SUPPLEMENTS

108.1.1 Dietary Supplement Health and Education Act of 1994

108.1.1.1 Core Provisions

Botanical products (medicinal herbs), vitamins, and minerals are regulated under the *Dietary Supplement Health and Education Act of 1994* (DSHEA)—a bill that exempts these products from meaningful FDA regulation. The DSHEA created a special category for nutritional supplements that exempts them from the scrutiny applied to other foods. The DSHEA also states that products not already sold as drugs can now be sold as *dietary supplements*. Put another way, if a manufacturer is willing to call its product by another name—“dietary supplement” rather than “drug”—the product can qualify for regulation under the DSHEA, thereby avoiding regulation under the more stringent Food, Drug, and Cosmetic Act. As discussed in [Chapter 3](#), the Food, Drug, and Cosmetic Act requires that conventional drugs—both prescription and over-the-counter agents—undergo rigorous evaluation of safety and

efficacy prior to receiving FDA approval for marketing. The DSHEA imposes no such requirements on “dietary supplements.” That is, dietary supplements can be manufactured and marketed without giving the FDA any proof they are safe or effective. All the manufacturer must do is notify the FDA of efficacy claims. If a product eventually proves harmful or makes false claims, the FDA does have the authority to intervene—but only *after* the product had been released for marketing. Furthermore, in order to challenge a claim of efficacy, the FDA must file suit in court; the challenge cannot be made through a simple administrative procedure. As you might guess, the DSHEA was created in response to intensive lobbying from the multibillion-dollar dietary supplement industry, which wanted to minimize government oversight.

108.1.1.2 Package Labeling

The DSHEA does impose some restrictions on labeling. All herbal products must be labeled as “dietary supplements.” In addition, the label must not claim that the product can be used to diagnose, prevent, treat, or cure a disease. In fact, it must state the opposite: *This product is not intended to diagnose, treat, cure, or prevent any disease*. However, the label is allowed to make claims about the product's ability to favorably influence *body structure or function*. Put another way, the label can insinuate specific benefits, but can't make overt claims. By way of illustration, labels *can* bear statements like these:

- Helps promote urinary tract health
- Helps maintain cardiovascular function
- Energizes and rejuvenates
- Reduces stress and frustration
- Improves absentmindedness
- Supports the immune system

But labels *can't* bear statements or terms like these:

- Protects against cancer
- Reduces pain and stiffness of arthritis
- Lowers cholesterol
- Supports the body's antiviral capabilities

- Improves symptoms of Alzheimer's disease
- Relieves menopausal hot flashes
- “Antibiotic,” “antiseptic,” “antidepressant,” “laxative,” or “diuretic”

If all of this sounds like semantic hair splitting—it largely is. Furthermore, regardless of what the label says, common sense says that people *will* take herbal products with the intent to prevent or treat disease.

Under the provisions of the DSHEA, there is no assurance that a product actually contains what the label proclaims: the package may contain ingredients that are *not* listed, or it may *lack* ingredients that *are* listed. These shortcomings and others have been addressed by the Current Good Manufacturing Practices ruling, issued by the FDA in 2007 (see below).

108.1.1.3 Adverse Effects

With dietary supplements, as with conventional drugs, the manufacturer is responsible for safety. However, the similarity ends there. Under the DSHEA, a product is presumed safe until proved hazardous. Furthermore, the burden for proving danger lies with the consumer and the FDA. With conventional drugs, opposite logic and regulations apply: Drugs are presumed dangerous until rigorous testing by the manufacturer reveals an absence of serious toxicity. Because of this system, the number of dangerous drugs that reach the market is kept to a minimum. Ask yourself, “Which product would I be more comfortable using—one that has been tested for adverse effects *before* I take it, or one that is evaluated for toxicity only *after* it caused me harm?”

108.1.1.4 Impurities, Adulterants, and Variability

The DSHEA does not address the issues of impurities, adulterants, or variability. As a result, dangerous products have been allowed to reach consumers. A few examples illustrate the problem:

- A combination product used to “cleanse the bowel” caused life-threatening heart block. Analysis revealed contamination with *Digitalis lanata*, a plant with powerful effects on the heart.
- Among 125 ephedra products analyzed by the FDA, ephedrine content per dose ranged from undetectable to 110 mg. Also, some products had 6 to 20 additional ingredients.

1262

1263

- Testing of 10 brands of ginseng products revealed a 20-fold variation in ginsenoside content.
- When the California Department of Health Sciences analyzed 243 Asian patent medicines, they found 24 containing lead, 35 containing mercury, and 36 containing arsenic—all in levels above those permitted in drugs. Seven percent of the products were adulterated with undeclared pharmaceuticals, including ephedrine, chlorphen-iramine, methyltestosterone, and phenacetin.

As discussed below, the Current Good Manufacturing Practices ruling, issued by the FDA in 2007, should prevent the sale of such products in the future.

108.1.1.5 Other Provisions

DSHEA directed the Secretary of Health and Human Services to establish an office within the National Institutes of Health to focus on research regarding CAM. In response, the Secretary created the National Center for Complementary and Alternative Medicine mentioned above.

DSHEA allows retail stores to display promotional material to inform consumers about health-related benefits of products, as long as the material is not false or misleading, and is not displayed close to the product itself.

108.1.2 Current Good Manufacturing Practices Ruling

In June 2007, the FDA issued a set of standards to regulate manufacturing and labeling of dietary supplements. These standards, referred to as Current Good Manufacturing Practices (CGMPs), are designed to ensure that dietary supplements be devoid of adulterants, contaminants, and impurities, and that package labels accurately reflect the identity, purity, quality, and strength of what's inside. In addition, the label should indicate not only active ingredients but also inactive ingredients. The CGMPs also mandate that manufacturers establish quality-control procedures, with the objective of preventing mislabeled, underfilled, or overfilled formulations; variations in tablet size, color, or potency; and contamination with drugs, bacteria, pesticides, glass, lead, and other potential contaminants. Implementation will be phased in over 3 years, with deadlines based on company size as follows: CGMPs must be in place by June 2008 for the largest companies (500 employees or more), by June 2009 for those with 21 to 499 employees, and by June 2010 for those with less than 20 employees. Unfortunately, even with the new standards and rules, there is still no assurance that dietary supplements will be either safe or effective—but at least we will have improved confidence regarding package contents.

^{108.1.3} Dietary Supplement and Nonprescription Drug Consumer Protection Act

This act, passed in 2006, mandates reporting of serious adverse events for nonprescription drugs and dietary supplements. The following events should be reported: deaths, hospitalizations, life-threatening experiences, persistent or significant disabilities, and birth defects. Manufacturers and distributors must report these to the FDA within 15 days. Reports can be filed by telephone or by mail, or through the MedWatch program (see [Chapter 7](#)).

^{108.1.4} A Comment on the Regulatory Status of Dietary Supplements

Unlike conventional drugs, herbal products and other dietary supplements are not regulated for either safety and efficacy. Many of these products have constituents that can produce profound pharmacologic effects, both beneficial and adverse. Nonetheless, reliable information on clinical effects is largely lacking. Congress does not allow conventional drugs to be dispensed in the absence of extensive testing, but has made an exception for the supplements. This is both irrational and dangerous. After all, whether you ingest ephedrine in the form of a pill or in the form of Ma huang, it's still ephedrine, and it's still going to have powerful effects. Clearly, herbal products should be evaluated and regulated in essentially the same manner as conventional drugs. An editorial in the *New England Journal of Medicine* (339:839–841, 1998) addressed this issue with eloquence. Here's the concluding paragraph:

It is time for the scientific community to stop giving alternative medicine a free ride. There cannot be two kinds of medicine—conventional and alternative. There is only medicine that has been adequately tested and medicine that has not, medicine that works and medicine that may or may not work. Once a treatment has been tested rigorously, it no longer matters whether it was considered alternative at the outset. If it is found to be reasonably safe and effective, it will be accepted. But assertions, speculation, and testimonials do not substitute for evidence. Alternative treatments should be subjected to scientific testing no less rigorous than that required for conventional treatments.

^{10...} PRIVATE QUALITY CERTIFICATION PROGRAMS

Rather than wait for implementation of CGMPs, four private organizations—the U.S. Pharmacopeia (USP), ConsumerLab, the Natural Products Association, and NSF International (formerly known as the National Sanitation Foundation)—have already begun testing dietary supplements for quality. A “seal of approval” is given to products that meet their standards, which are very similar to the CGMPs described above. The USP standards are enforceable by the FDA.

All four organizations require manufacturers to pay for the tests, and all four report on the following:

- Current Good Manufacturing Practices
- Purity
- Identity
- Potency
- Dissolution
- Accuracy of Labeling

In addition, two organizations—the USP and ConsumerLab—report on postapproval surveillance.

1263

TABLE 107-2 Concentrations of Active Agents in Some Standardized Herbal Preparations

1264

Herb	Amount of Active Agent
Black cohosh	2.5% Triterpene glycosides
Echinacea	4% Phenolic compounds
Feverfew	0.2% Parthenolide
<i>Ginkgo biloba</i>	24% Ginkgo flavenoids, 6% terpenoids
St. John's wort	0.3% Hypericin
Valerian root	1% Valerianic acid

10... STANDARDIZATION OF HERBAL PRODUCTS

With herbal products, there is often uncertainty about the amounts of active ingredients. The concentration of active ingredients in herbal crops can vary from year to year and from place to place. Reasons include differences in sunshine, rainfall, temperature, and soil nutrients. As a result, the potency of herbal products can vary widely.

Variability can be reduced through standardization, a three-step process in which the manufacturer (1) prepares an *extract* of plant parts, (2) analyzes the extract for one or two known active ingredients, and (3) dilutes or concentrates the extract such that the final product contains a predetermined amount of the active ingredient(s). The objective is to achieve therapeutic equivalence from batch to batch made by the same manufacturer, and among batches made by

different manufacturers. [Table 107-2](#) lists the concentrations of active ingredients in some standardized preparations.

Standardization has two important benefits. First, it permits accurate dosing. Second, it permits extrapolation of data obtained in clinical trials to the public in general.

Unfortunately, standardization also has drawbacks. The extraction process might destroy active compounds. Furthermore, the process may fail to extract as-yet unidentified active agents, and hence the extract may have a different spectrum of effects than the intact plant. To the extent this is true, historic data obtained with whole plants will lose some value as a basis for helping us understand clinical responses to the standardized extract.

^{10...} ADVERSE INTERACTIONS WITH CONVENTIONAL DRUGS

Herbal products and other dietary supplements can interact with conventional drugs, sometimes with disastrous results. The principal concerns are increased toxicity and decreased therapeutic effects. Clinicians and consumers should be alert to these possibilities. Unfortunately, with many supplements, reliable information on adverse interactions is lacking—in large part because potential interactions have not been systematically studied. Hence, if a patient is taking a conventional medication and a dietary supplement, and therapeutic effects are lost or toxicity appears, it may be impossible to say for sure that the supplement was (or was not) responsible.

A few important interactions *have* been identified, including the following:

- St. John's wort can induce the 3A4 isozyme of cytochrome P450, and can thereby accelerate the metabolism of many drugs, causing a loss of therapeutic effects.
- Several herbal products, including *Ginkgo biloba*, feverfew, and garlic, suppress platelet aggregation, and hence can increase the risk of bleeding in patients receiving antiplatelet drugs (eg, aspirin) or anticoagulants (eg, warfarin, heparin).
- Ma huang (ephedra) contains ephedrine, a compound that can elevate blood pressure and stimulate the heart and central nervous system (CNS). Accordingly, ephedra can intensify the effects of pressor agents, cardiac stimulants, and CNS stimulants, and counteract the beneficial effects of antihypertensive drugs and CNS depressants.

These interactions, at least, can be avoided—provided the prescriber is aware of them, and provided the patient informs the prescriber about supplement use. Unfortunately, up to 70% of patients neglect to do so.

^{10...} SOME COMMONLY USED DIETARY SUPPLEMENTS

^{108.5.1} Black Cohosh

^{108.5.1.1} Uses.

Black cohosh (*Cimicifuga racemosa*) is used for treating symptoms of menopause, including hot flashes, vaginal dryness, palpitations, depression, irritability, and sleep disturbance. The preparation should *not* be used to reduce hot flashes caused by tamoxifen and other selective estrogen receptor modulators (SERMs).

^{108.5.1.2} Actions.

How black cohosh works is unknown. At one time, we believed it suppressed release of luteinizing hormone (LH). However, clinical studies have failed to show an effect on female hormones, including LH, estradiol, prolactin, and follicle-stimulating hormone. In laboratory studies, black cohosh does not interact with estrogen receptors: It doesn't bind these receptors, up-regulate estrogen-dependent genes, or promote growth of estrogen-dependent tumors (at least in animals). In the laboratory, black cohosh inhibits the growth of prostate cancer cells.

^{108.5.1.3} Effectiveness.

Black cohosh has been evaluated extensively in Germany, where most studies indicate it can effectively relieve menopausal symptoms. In fact, some studies have shown black cohosh to be as beneficial as estrogen replacement therapy (ERT), the conventional treatment for menopausal symptoms. Unlike ERT, black cohosh has not been evaluated for long-term use (ie, beyond 6 months). Many commercial products include St. John's wort in their formulations to address the psychological symptoms associated with menopause. These products should be avoided due to the large number of drug interactions associated with St. John's wort (see below). The American College of Obstetricians and Gynecologists supports the short-term use of black cohosh for relieving menopausal symptoms.

^{108.5.1.4} Adverse Effects.

The German Commission E states that black cohosh is safe for routine use. Gastrointestinal symptoms are most common. Other possible adverse effects include rash, headache, dizziness, weight gain, and cramps. Rarely, black cohosh has been associated with *liver toxicity*, but a direct causal link has not been established. Due to lack of scientific information on long-term effects in humans, the German Commission E recommends using black cohosh for no more

1264

1265

than 6 months. Because of its estrogenic effects, black cohosh should not be taken during pregnancy, especially during the first and second trimesters.

108.5.1.5 Interactions with Conventional Drugs.

Black cohosh may potentiate the hypotensive effects of antihypertensive drugs as well as the hypoglycemic effects of insulin and oral hypoglycemics. In women under anesthesia, the herb has caused hypotension that was difficult to manage. Owing to its estrogenic actions, black cohosh may potentiate the effects of estrogens used for hormone replacement or contraception, and may reduce the effects of estrogen receptor antagonists. Black cohosh should be used with caution in patients taking other drugs that may harm the liver.

108.5.1.6 Comments.

Black cohosh has a long history in America. The herb was used by Native Americans and later by American colonists. Between 1820 and 1926, it was listed as an official drug in the U.S. Pharmacopeia.

Users must not confuse black cohosh with blue cohosh (Caulophyllum thalictroides). Although blue cohosh has legitimate uses, including promotion of menstruation and labor, it is very different from black cohosh and potentially more dangerous. Blue cohosh can elevate blood pressure, increase intestinal motility, and accelerate respiration. More importantly, it can induce uterine contractions, and hence should be avoided during pregnancy, except at term. Some commercial products contain both black cohosh and blue cohosh. Women who only want black cohosh should avoid these products.

108.5.2 Coenzyme Q-10

108.5.2.1 Uses.

Coenzyme Q-10 (ubiquinone, CoQ-10) is used to treat heart failure, muscle injury caused by HMG-CoA reductase inhibitors (statins), and mitochondrial encephalomyopathies (ie, muscle and nervous system injury caused by deranged mitochondrial metabolism).

108.5.2.2 Actions.

CoQ-10 is found in nearly every cell of the body. The highest concentrations are found in the heart, liver, kidney, and pancreas. CoQ-10 is a potent antioxidant and participates in many metabolic pathways, most notably production of ATP. Clinical benefits of CoQ-10 appear to result primarily from antioxidant actions supporting production of ATP.

108.5.2.3 Effectiveness.

In patients with documented CoQ-10 deficiency, replacement therapy with CoQ-10 offers clear benefits.

Effectiveness in heart failure is limited. Although CoQ-10 can improve quality of life, it does not seem to improve objective measures (ejection fraction and blood pressure). CoQ-10 has no role in heart failure as monotherapy, but adding it to conventional therapy may be of help.

One formulation of CoQ-10—UbiQGel—has been granted orphan drug status for treatment of mitochondrial encephalomyopathies.

The use of CoQ-10 to prevent statin-induced myopathies is anecdotal; hard evidence of benefits is lacking.

108.5.2.4 Adverse Effects.

CoQ-10 is well tolerated. High doses may produce GI disturbances, including gastritis, reduced appetite, nausea, and diarrhea.

108.5.2.5 Interactions with Conventional Drugs.

CoQ-10 is structurally similar to vitamin K₂, and hence may antagonize the effects of warfarin.

Biosynthesis of CoQ-10 shares a common pathway with cholesterol. As a result, drugs like the statins, which inhibit synthesis of cholesterol, can also inhibit synthesis of CoQ-10, causing levels of endogenous CoQ-10 to decline. (Statin-induced reductions in CoQ-10 may explain why statins cause muscle injury.)

108.5.3 Cranberry Juice

108.5.3.1 Uses.

Cranberry juice is used to prevent urinary tract infections (UTIs) and to decrease urine odor in patients with urinary incontinence.

108.5.3.2 Actions.

Benefits derive from the presence of proanthocyanidins, a group of compounds that prevent bacteria from adhering to the urinary tract wall. Bacteria that have already attached themselves are not affected. Cranberry juice does not acidify the urine as previously thought.

108.5.3.3 Effectiveness.

Daily consumption of cranberry juice can *prevent* recurrent UTIs, but only in certain age groups. Specifically, it appears to benefit elderly women and women in their teens or 20s, not older adults or young girls. Furthermore, although cranberry juice can prevent UTIs, it is not effective as treatment for an existing infection. In patients with urinary incontinence, cranberry juice can reduce unpleasant odor. Little is known about the efficacy of cranberry-extract capsules. Accordingly, cranberry juice itself is the preferred formulation.

108.5.3.4 Adverse Effects.

Drinking more than 1 L/day may increase the risk of GI upset and formation of uric acid kidney stones.

108.5.3.5 Interactions with Conventional Drugs.

There is some evidence that cranberry juice may increase the risk of bleeding in patients taking warfarin. Accordingly, these patients should be monitored closely.

108.5.4 Echinacea

108.5.4.1 Uses.

Echinacea (*Echinacea angustifolia*, *E. purpurea*, *E. pallida*) is used orally and topically. Oral echinacea is taken to stimulate immune function, suppress inflammation, and treat viral infections, including influenza and the common cold. Topical echinacea is used to treat wounds, burns, eczema, psoriasis, and herpes simplex infections. Echinacea was listed in the National Formulary from 1916 to 1950, but fell from favor owing to development of antibiotics and a lack of scientific data to support its use.

108.5.4.2 Actions.

Active ingredients in echinacea preparations include cichoric acid, polysaccharides, flavenoids, and essential oils. These ingredients produce antiviral, anti-inflammatory, and immunostimulant effects through a combination of actions, including mobilization of phagocytes, stimulation of T-lymphocyte proliferation, stimulation of interferon and tumor necrosis factor production, and inhibition of hyaluronidase, a proinflammatory enzyme.

108.5.4.3 Effectiveness.

Although echinacea is taken widely to prevent and treat colds, its efficacy is highly questionable. Recent randomized, placebo-controlled trials designed to evaluate the ability of echinacea to *prevent* colds found no effect on (1) the time to developing an upper respiratory infection (URI); (2) the incidence, duration, or severity of URIs that did develop; or (3) development of experimentally induced URIs. Other recent trials conducted on adults and children who already had a URI found echinacea no better than placebo at reducing either the duration or severity of symptoms.

108.5.4.4 Adverse Effects.

Very few adverse effects have been reported. The most common complaint is unpleasant taste. Fever, nausea, and vomiting occur infrequently.

Rarely, echinacea causes allergic reactions, including acute asthma, urticaria, angioedema, and anaphylaxis. At the 2000 meeting of the American Academy of Allergy, Asthma, and Immunology, nearly two dozen cases of echinacea allergy were reported. Individuals with atopy (a genetic tendency toward allergic conditions) appear at increased risk of reacting to echinacea: Of the atopic patients tested, 2 in 10 had a positive skin test, even though they had never taken the herb. Echinacea belongs to the daisy family of plants, whose members include ragweed, asters, chamomile, and chrysanthemums. People allergic to any of these plants are at increased risk of reacting to echinacea.

Because echinacea can stimulate the immune system, it would be prudent to avoid the drug in patients with autoimmune diseases, such as lupus erythematosus or rheumatoid arthritis.

Although short-term exposure to echinacea stimulates immune function, long-term exposure can *suppress* immune function. Accordingly, long-term therapy should be avoided in immunocompromised patients, including those with HIV infection. In addition, prolonged therapy should be avoided in people with tuberculosis and other chronic infections that require optimal immune function for cure.

108.5.4.5 Interactions with Conventional Drugs.

By stimulating the immune system, echinacea can oppose the effects of immunosuppressant drugs. Conversely, by suppressing immune function (in response to long-term use), echinacea can compromise drug therapy of tuberculosis, cancer, and HIV infection.

108.5.5 Feverfew

108.5.5.1 Uses.

Feverfew (*Tanacetum parthenium*) is used primarily for prophylaxis of migraine.

108.5.5.2 Actions.

The principal active agent in feverfew is *parthenolide*, a compound found in feverfew leaves. How parthenolide suppresses migraine is not well understood. Possibilities include inhibition of vasoconstriction in the brain, suppression of serotonin release from platelets and leukocytes, and suppression of inflammation secondary to inhibition of arachidonic acid release.

108.5.5.3 Effectiveness.

Clinical studies and historic evidence suggest that feverfew does indeed benefit patients with migraine. When taken prophylactically, the herb can reduce the frequency of attacks and the severity of symptoms (nausea, photophobia, phonophobia, and pain). Unfortunately, feverfew is less effective when taken to abort an ongoing attack. Furthermore, the doses required are much higher than those for prophylaxis. There is no reliable evidence that feverfew can benefit patients with rheumatoid arthritis or other inflammatory conditions.

108.5.5.4 Adverse Effects.

Feverfew is very well tolerated. No serious adverse effects have been reported—although long-term studies of safety are lacking. Mild reactions include abdominal pain, indigestion, diarrhea, flatulence, nausea, and vomiting. Chewing feverfew leaves—a practice rare today—can cause oral ulceration, tongue irritation, and swollen lips. Some patients develop *post-feverfew syndrome*, characterized by nervousness, fatigue, insomnia, tension headache, and joint pain or stiffness. Feverfew may be better tolerated than conventional prophylactic therapies. Feverfew belongs to the same plant family as echinacea. Accordingly, individuals allergic to ragweed, chrysanthemums, daisies, and marigolds may also be allergic to feverfew. By suppressing release of arachidonic acid in platelets, feverfew can decrease platelet aggregation, and can thereby pose a risk of bleeding. Accordingly, the product should be discontinued 2 weeks before elective surgery.

108.5.5.5 Interactions with Conventional Drugs.

By suppressing platelet aggregation, feverfew can increase the risk of bleeding in patients taking antiplatelet drugs (eg, aspirin) or anticoagulants (eg, warfarin, heparin).

108.5.5.6 Comments.

There is great variability in feverfew products. Some contain little or no active ingredient.

108.5.6 Flaxseed

108.5.6.1 Uses.

Flaxseed powders are used to treat constipation and dyslipidemias. Flaxseed also represents a vegetarian source of omega-3 fatty acids.

108.5.6.2 Actions.

Ground flaxseed provides soluble plant fiber and alpha-linolenic acid. Like other high-fiber products, flaxseed can reduce serum cholesterol.

Flaxseed is an important food source of phytoestrogens called lignans. In the colon, bacteria convert these lignans into enterolactone and enterodiol, compounds that have both mild estrogenic and antiestrogenic actions. The antiestrogenic actions can decrease cellular proliferation in mammary tissue.

108.5.6.3 Effectiveness.

Like other fiber products, flaxseed decreases plasma levels of total cholesterol (5% to 9%) and low-density lipoprotein (LDL) cholesterol (8% to 18%), but does not affect high-density lipoprotein (HDL) cholesterol or triglycerides. In contrast, *defatted* flaxseed may *increase* triglyceride levels, and hence should be avoided by patients with hypertriglyceridemia. Owing to its fiber content, flaxseed acts like a bulk-forming laxative to relieve constipation.

108.5.6.4 Adverse Effects.

Like other sources of dietary fiber, flaxseed can cause GI effects, including bloating, flatulence, and abdominal discomfort.

108.5.6.5 Interactions with Conventional Drugs.

Flaxseed may reduce the absorption of conventional medications, and hence should be taken 1 hour before or 2 hours after these drugs.

108.5.7 Garlic

108.5.7.1 Uses.

Garlic (*Allium sativum*) is used primarily for effects on the cardiovascular system. The herb is taken to reduce levels of triglycerides and LDL cholesterol, and to raise levels of HDL cholesterol. Garlic is also employed to reduce blood pressure, suppress platelet aggregation, increase arterial elasticity, and decrease formation of atherosclerotic plaque. In addition, garlic has been used for antimicrobial and anticancer effects.

108.5.7.2 Actions.

Beneficial effects result from the actions of sulfides in garlic oil. Intact garlic cells contain *alliin*, an odorless amino acid. When garlic cells are crushed, they release allinase, an enzyme that converts alliin into *allicin*. Allicin is the major active agent in garlic oil and the compound that gives garlic its distinctive aroma. In addition to allicin, garlic oil contains *ajoenes* (pronounced AH-ho-weens), biologically active compounds that contribute to beneficial effects.

Garlic is thought to lower cholesterol levels by interfering with cholesterol synthesis in the liver. Several key steps in the synthetic pathway are affected. There is conflicting evidence regarding inhibition of HMG-CoA reductase, the rate-limiting enzyme in cholesterol synthesis and the enzyme that “statin” drugs inhibit.

Antiplatelet effects, which are well documented, result in part from inhibiting thromboxane synthesis. Methylallyltrisulfide is the chemical in garlic believed responsible. In addition, garlic may suppress platelet aggregation by disrupting calcium-dependent processes. Coagulation is also affected by the ajoenes, which have antithrombotic actions and may also stimulate fibrinolysis.

Lowering of blood pressure may be explained by garlic's demonstrated ability to increase the activity of nitric oxide synthase, the enzyme in blood vessels that makes nitric oxide. Nitric oxide, also known as endothelium-derived relaxant factor, is a powerful vasodilator.

108.5.7.3 Effectiveness.

Garlic can produce favorable effects on plasma lipids, and possibly on blood pressure. However, benefits depend on the quality of the preparation. When a high-quality preparation is used, garlic can decrease total cholesterol by 6% to 9%, LDL cholesterol by about 11%, and

triglycerides by 25%. In addition, garlic can produce a small increase in HDL cholesterol. Although garlic is taken to reduce blood pressure, benefits appear modest at best.

The effectiveness of garlic products is determined by their ability to yield allicin. Since both allicin and allinase (the enzyme that makes allicin) are destroyed by heat, cooked garlic is not effective. Benefits of raw garlic are variable. Furthermore, because allicin is inactivated by acid in the stomach, large doses (1 to 2 whole cloves twice daily) are required. Best results are produced with an enteric-coated, dried preparation that contains a specified amount of alliin and allinase. Unfortunately, a German study has shown that only 5 of 18 common garlic products contain allicin in effective amounts.

108.5.7.4 Adverse Effects.

Garlic is generally well tolerated. The most common side effects are unpleasant taste and bad breath. Rarely, garlic causes heartburn, flatulence, nausea, vomiting, diarrhea, and a burning sensation in the mouth. These effects are most pronounced with raw garlic and in people who don't eat garlic often. Patients suffering from infectious or inflammatory GI disorders should avoid garlic owing to its potential for GI irritation.

108.5.7.5 Interactions with Conventional Drugs.

Garlic has significant antiplatelet effects. Accordingly, it can increase the risk of bleeding in patients taking antiplatelet drugs (eg, aspirin) or anticoagulants (eg, warfarin, heparin). Garlic can reduce levels of at least two drugs: cyclosporine (an immunosuppressant) and saquinavir (a protease inhibitor used to treat HIV infection).

108.5.8 Ginger Root

108.5.8.1 Uses.

Ginger root (*Zingiber officinale*) is used primarily to treat vertigo and to suppress nausea and vomiting associated with motion sickness, morning sickness, seasickness, and general anesthesia. In addition, ginger has anti-inflammatory and analgesic properties that may help people with arthritis and other chronic inflammatory conditions. Some practitioners use ginger for URIs, although proof of efficacy is lacking.

108.5.8.2 Actions.

The mechanism by which ginger suppresses nausea and vomiting is unclear. A good possibility is blockade of serotonin (5-hydroxytryptamine₃, or 5-HT₃) receptors located in the chemoreceptor trigger zone of the brain and on afferent vagal neurons in the GI tract.

Activation of these receptors triggers emesis. Conversely, blockade of these receptors suppresses emesis. In fact, drugs that block 5-HT₃ receptors (eg, ondansetron [Zofran]) are the most effective antiemetics available. Galanolactone, a major constituent of ginger, can block 5-HT₃ receptors *in vitro*, suggesting that receptor blockade may underlie antiemetic effects. Other actions that may contribute to beneficial GI effects include stimulation of intestinal motility, salivation, and gastric mucus production, and suppression of GI spasm secondary to anticholinergic and antihistaminic actions.

The anti-inflammatory effects of ginger have been attributed to inhibiting synthesis of prostaglandins and leukotrienes, which are powerful inflammatory mediators.

How ginger may reduce vertigo is unknown.

108.5.8.3 Effectiveness.

Over the years, enough evidence has been collected to support the benefits of ginger root for prevention and treatment of motion sickness, morning sickness, seasickness, and postoperative nausea and vomiting (in the absence of opioids). Benefits in morning sickness are comparable to those of vitamin B₆, but may take up to 3 days to develop. In patients with rheumatoid arthritis, ginger root appears to reduce pain, improve joint mobility, and decrease swelling and morning stiffness.

108.5.8.4 Adverse Effects.

Ginger is very well tolerated. Severe toxicity has never been reported—although hugely excessive doses (above 5 gm/day) have the potential to cause CNS depression and cardiac dysrhythmias. Huge doses may also cause GI disturbances.

Ginger should be used with caution during pregnancy. There is evidence that high doses can stimulate the uterus, and might thereby cause spontaneous abortion, although there are no reports of this ever happening. There is some concern that ginger may affect fetal sex hormones. Because of these concerns, intake should be limited to usual therapeutic doses (eg, 1 to 2 gm dried root/day).

108.5.8.5 Interactions with Conventional Drugs.

Ginger can inhibit production of thromboxane by platelets, and can thereby suppress platelet aggregation. Accordingly, ginger can increase the risk of bleeding in patients receiving antiplatelet drugs (eg, aspirin) or anticoagulants (eg, warfarin, heparin). Ginger can lower

blood sugar, and hence may potentiate the hypoglycemic effects of insulin and other drugs used to treat diabetes.

1267

108.5.9 Ginkgo biloba

1268

108.5.9.1 Uses.

Ginkgo (*Ginkgo biloba*) can increase pain-free walking distance in patients with peripheral arterial disease. Although the drug has been taken to improve age-related memory impairment and senile dementia, proof of efficacy is lacking.

108.5.9.2 Preparations.

Medicinal ginkgo is prepared by acetone extraction of leaves from the *Ginkgo biloba* tree. These leaves contain two classes of active compounds: *flavenoids* (ginkgo flavone glycosides) and *terpenoids* (ginkgolides, bilobalide). *Ginkgo biloba extracts* (GBEs) are standardized to contain 24% flavenoids and 6% terpenoids. Daily oral doses of standardized GBE range from 60 to 240 mg.

108.5.9.3 Actions.

Most benefits derive from improved blood flow secondary to ginkgo-induced vasodilation. Further benefits may derive from reducing capillary fragility and from scavenging free radicals. (Scavenging free radicals helps protect blood vessels from injury.) GBEs also suppresses production of platelet-activating factor (PAF), a mediator of platelet aggregation, bronchospasm, and other processes. Reduced PAF production may help protect against thrombosis as well as bronchospasm and other allergic disorders.

108.5.9.4 Effectiveness.

In patients with occlusive arterial disease of the legs (Fontain stage IIb) or intermittent claudication, ginkgo can improve local blood flow and increase pain-free walking distance.

What about benefits in dementia? In a large placebo-controlled trial—the Ginkgo Evaluation of Memory (GEM) study, sponsored by the National Institutes of Health—GBE failed to prevent dementia of any sort, including Alzheimer's disease. This study enrolled over 3000 participants, age 75 or older. Half received a GBE formulation (120 mg twice daily) and the other half received a placebo. The result? After 5 years of treatment, the incidence of dementia was nearly identical in both groups.

108.5.9.5 Adverse Effects.

Ginkgo is generally well tolerated. In some patients, it causes stomach upset, headache, dizziness, or vertigo, all of which can be minimized by avoiding rapid increases in dosage. There have been cases reports of spontaneous bleeding, although no bleeding was observed in the GEM study.

108.5.9.6 Interactions with Conventional Drugs.

Ginkgo may suppress coagulation. Accordingly, it should be used with caution in patients taking antiplatelet drugs (eg, aspirin) or anticoagulants (eg, warfarin, heparin).

There is concern that ginkgo may promote seizures. Accordingly, the herb should be avoided by patients at risk for seizures, including those taking drugs that can lower the seizure threshold (eg, antipsychotics, antidepressants, cholinesterase inhibitors, decongestants, first-generation antihistamines, and systemic glucocorticoids).

108.... Glucosamine

108.5.1... Uses.

Glucosamine—simply glucose with an amino group attached—is available as two salts: glucosamine sulfate and glucosamine hydrochloride. These agents are used widely to *treat* osteoarthritis of the knee, hip, and wrist.

108.5.1... Actions.

Glucosamine is employed by the body in the synthesis of cartilage and synovial fluid. When given to people with osteoarthritis, glucosamine may help in several ways. First, it can act as a substrate for making cartilage and synovial fluid. Second, it can stimulate the activity of chondrocytes, the cells in joints that make cartilage and synovial fluid. And third, it can suppress production of cytokines that mediate joint inflammation and cartilage degradation.

108.5.1... Effectiveness.

Studies on the efficacy of glucosamine in osteoarthritis have yielded mixed results. These differences may be due in part to the form of glucosamine used: glucosamine sulfate or glucosamine hydrochloride. In many studies using glucosamine *sulfate*, treatment reduced pain scores (by 28% to 40%) and increased joint functionality (by 21% to 46%). By contrast, in a major study using glucosamine *hydrochloride*—the Glucosamine/chondroitin Arthritis

Intervention Trial (GAIT)—pain reduction with glucosamine was no better than with placebo. These differences suggest that glucosamine sulfate may be superior to glucosamine hydrochloride. Why might the sulfate work better? Because sulfate is an important cofactor in cartilage synthesis.

Glucosamine is often used in combination with *chondroitin sulfate*. However, the effectiveness of combination products has not been proved.

108.5.1... Adverse Effects.

The most common side effects are GI disturbances, such as nausea and heartburn. Since commercial glucosamine is produced from the exoskeletons of shellfish (shrimp), glucosamine should be used with caution in patients with shellfish allergy. In theory, glucosamine can raise blood levels of glucose, but this has not been observed in clinical trials.

108.5.1... Interactions with Conventional Drugs.

Several case reports suggest glucosamine may increase the risk of bleeding. Accordingly, exercise caution in patients taking warfarin and other anticoagulants.

108.... Green Tea

108.5.1... Uses.

Green tea (*Camellia sinensis*) and green tea extracts have been used to lose weight, improve mental clarity, and prevent and treat cancers of the stomach, skin, bladder, and breast.

108.5.1... Actions.

The mechanism underlying beneficial effects is poorly understood, and probably multifactorial. Polyphenols in green tea may underlie anti-inflammatory, chemoprotective, and antioxidant effects. Chemoprotection may also stem from epigallocatechin-3-gallate (EGCG), a compound in green tea extracts. The caffeine in green tea may be responsible for weight loss and improved mental clarity.

108.5.1... Effectiveness.

Data on green tea efficacy are limited. Drinking green tea throughout the day can improve mental clarity, and may help with weight loss. In both cases, any benefits are probably due to caffeine, and not a substance unique to green tea. Studies done in animals and cultured cancer cells have shown that green tea and EGCG may prevent or slow the growth of certain cancers.

Also, there is a small body of evidence indicating that drinking green tea may help prevent recurrence in early-stage breast cancer.

108.5.1... Adverse Effects.

Moderate consumption appears to be safe. As with other caffeine-containing products, overconsumption may result in headache, nausea, anxiety, insomnia, increased heart rate, and increased urination. Fourteen cases of hepatotoxicity have been reported, primarily in people using green tea extracts. The mechanism of the hepatotoxicity remains unknown.

1268

108.5.1... Interactions with Conventional Drugs.

1269

There is a long list of potential drug interactions. Green tea should be consumed with caution by patients taking vasodilators, stimulants and other psychoactive medications, and medications with a known risk for liver damage. Green tea contains a small amount of vitamin K, which may decrease the anticoagulant effects of warfarin.

108.... Probiotics

108.5.1... Uses.

Probiotics are dietary supplements composed of potentially beneficial bacteria or yeasts. These preparations typically contain two types of bacteria—lactobacilli and bifidobacteria—as well as *Saccharomyces boulardii*, a specific strain of yeast. All of these microorganisms are normal components of the gut flora. The *bacteria* in probiotics can help treat irritable bowel syndrome (IBS), ulcerative colitis, antibiotic-associated diarrhea (AAD), and, in children, rotavirus diarrhea. Products containing *S. boulardii* are used for AAD.

108.5.1... Actions.

Normal intestinal and colonic bacteria play several important roles: They help metabolize foods and some drugs; they promote nutrient absorption; and they reduce colonization of the gut by pathogenic bacteria. *Lactobacillus* and *Bifidobacterium* species adhere to the intestinal wall, and thereby prevent attachment of bacterial pathogens. They also control bacterial overgrowth by producing lactic acid, and to some degree by producing hydrogen peroxide. Benefits may also derive from increasing nonspecific cellular and humeral immunity. The yeast *S. boulardii* produces proteases that can degrade toxins produced by *C. difficile*. Benefits of *S. boulardii* in Crohn's disease derive in part by increasing intestinal secretion of immunoglobulin A.

108.5.1... Effectiveness.

One product—Culturelle—contains *Lactobacillus rhamnosus* and *Lactobacillus GG*. In young patients with rotavirus infection, Culturelle can reduce the duration of diarrhea. Early initiation of treatment is important. Treatment with other *Lactobacillus* species has shown similar results. In children with AAD, Culturelle can decrease stool frequency and improve stool consistency.

Another product—VSL#3—is composed of lactobacilli, bifidobacteria, and *Streptococcus thermophilus*. There is evidence that this product can induce remission of ulcerative colitis, perhaps in as many as 50% of patients. In patients with IBS, VSL#3 may reduce bloating and abdominal pain. However, the product does not improve bowel movement frequency or consistency.

Products containing *S. boulardii* may help prevent and treat AAD, including AAD caused by *C. difficile*. However, the evidence is inconclusive.

108.5.1... Adverse Effects.

Probiotics are generally well tolerated. Flatulence and bloating are the most common adverse effects. Infection of the blood with lactobacilli and fungi has been reported following ingestion of yogurt, but only in severely ill, immunocompromised patients taking broad-spectrum antibiotics long term. Fungicemia has occurred most often when packets of *S. boulardii* have been opened at the bedside in the intensive care unit.

108.5.1... Interactions with Conventional Drugs.

Probiotic activity may be altered by antibiotics and antifungals.

108.... Saw Palmetto

108.5.1... Uses.

Saw palmetto (*Serenoa repens*, *Sabal serrulata*) is taken to relieve urinary symptoms associated with benign prostatic hypertrophy (BPH). Benefits take months to develop. The product employed clinically is an extract made from berries of the American saw palmetto, a small palm native to the southeastern United States.

108.5.1... Actions.

How does saw palmetto affect prostate function? We don't know for sure. Reasonable possibilities include blockade of testosterone receptors, blockade of alpha-adrenergic receptors, and suppression of inflammation. Contrary to prior belief, the preparation does not seem to inhibit 5-alpha-reductase, the enzyme that converts testosterone into dihydrotestosterone (DHT), the active form of testosterone in the prostate. Saw palmetto does not reduce prostate size or serum levels of testosterone, DHT, or prostate-specific antigen (PSA).

108.5.1... Effectiveness.

Studies on the efficacy of saw palmetto in BPH have produced conflicting results. According to a trial reported in the February 9, 2006, issue of the *New England Journal of Medicine*, saw palmetto has no benefit in BPH. This double-blind trial enrolled 225 men and randomized them to receive saw palmetto extract or placebo. The result? After 1 year, all major clinical parameters—prostate size, maximal urinary flow rate, residual volume after voiding, quality of life, and serum PSA—were the same in the placebo and saw palmetto groups, indicating that saw palmetto had no effect. However, in several previous studies—also placebo-controlled and double-blind—saw palmetto compared favorably with conventional drugs for BPH: 5-alpha-reductase inhibitors (eg, finasteride [Proscar]) and alpha-adrenergic blockers (eg, tamsulosin [Flomax]). How can we explain these discrepancies? One possibility is that the results reflect variability among saw palmetto extracts. If so, then we need to identify the active component (if any) in saw palmetto, and standardize products on that basis. Future trials using standardized preparations could then clear up questions about whether saw palmetto is effective and/or safe.

108.5.1... Adverse Effects.

Saw palmetto is very well tolerated. Significant adverse effects have not been reported. Rarely, saw palmetto causes nausea or headache. Although antiandrogenic effects (eg, gynecomastia) have not been reported, it may be wise to monitor for them. Saw palmetto may have antiplatelet actions, but increased bleeding has not been reported.

Because of its antiandrogenic effects, saw palmetto represents a danger to the developing fetus. (Finasteride is classified in FDA Pregnancy Risk Category X.) Pregnant women should not ingest this herb.

108.5.1... Interactions with Conventional Drugs.

Because of its antiplatelet effects, saw palmetto should be used with caution in patients taking antiplatelet drugs (eg, aspirin) or anticoagulants (eg, warfarin, heparin).

108.... Soy

108.5.1... Uses.

Soy protein and soy isoflavones have several uses, including prevention of breast cancer and, in postmenopausal women, treatment of vasomotor symptoms (hot flashes) and prevention of osteoporosis.

108.5.1... Actions.

Soy is a member of the pea (legume) family. The major active components are phytoestrogens (isoflavones and lignans) and phytosterols (betasitosterol). Two isoflavones—genistein and daidzein—undergo enzymatic conversion to equol, a compound with estrogenic actions. About 50% of people lack the ability to produce equol. Soy isoflavones are structurally similar to estradiol (the major endogenous estrogen) and can bind with estrogen receptors. However, like the selective estrogen receptor modifiers (SERMs), isoflavones exert mixed estrogenic/antiestrogenic actions. In women with normal estrogen levels, soy isoflavones appear to *antagonize* endogenous estrogen. By contrast, in postmenopausal women, soy isoflavones act as estrogen agonists.

108.5.1... Effectiveness.

Clinical trials using soy-derived phytoestrogens to relieve menopausal hot flashes have yielded mixed results. Overall, the studies lean toward a reduction in hot flashes. How do we explain the negative studies? It may be that many of the women enrolled had a reduced ability to metabolize isoflavones to their active form.

Several epidemiologic studies infer that soy consumption may reduce the risk of developing breast cancer. In particular, studies have documented that Asian women who eat a diet high in soy are at reduced risk. However, clinical trials confirming this benefit are lacking.

Several studies suggest that isoflavones either increase bone mineral density or slow the progression of osteoporosis in peri- and postmenopausal women. However, in a paper titled *Effects of Soy on Health Outcomes*, published in 2006 by the Agency for Healthcare Research

and Quality, the authors caution against basing clinical decisions on current studies, owing to poor study design, inadequate study length, and small numbers of participants.

108.5.1... Adverse Effects.

Soy and soy extracts are very well tolerated. Gastrointestinal effects—bloating, nausea, constipation or diarrhea—are most common. Rarely, soy can cause migraine, probably because of its estrogenic effects. Large amounts of soy products may increase the risk of oxalate kidney stones. There have been several cases of goiter and hypothyroidism in infants who drank soy-based formula. Concerns that soy formulas might cause feminization of male infants have been dispelled by a 2008 review released by the American Academy of Pediatrics.

108.5.1... Interactions with Conventional Drugs.

Soy should not be combined with tamoxifen and other drugs that can block estrogen receptors. By killing intestinal flora, antibiotics may reduce conversion of isoflavones to their active form, thus decreasing the effects of soy.

108.... St. John's Wort

108.5.1... Uses.

St. John's wort (*Hypericum perforatum*) is used primarily for oral therapy of mild to moderate depression. The herb has also been used topically to manage local infection and orally to relieve pain and inflammation.

108.5.1... Actions.

Benefits of St. John's wort appear to derive from two compounds—hyperforin and hypericin—which are extracted from flowers of the plant. These compounds can decrease uptake of three neurotransmitters: serotonin, norepinephrine (NE), and dopamine. Blockade of serotonin and NE uptake mimic the actions of some conventional antidepressants. Early research attributed antidepressant effects to inhibition of monoamine oxidase (MAO). However, we now know that the degree of MAO inhibition is too small to explain clinical effects.

108.5.1... Effectiveness.

How effective is St. John's wort? At this time, it's hard to say. Although numerous studies have been conducted, evidence for efficacy is mixed, owing to poor study design, heterogeneous study populations, and variable hypericin content of the preparations used, as well as other confounding factors. The bottom line? For patients with *mild to moderate* major depression, St.

John's wort appears superior to placebo and equal to tricyclic antidepressants. For patients with *severe* depression, there is no convincing proof of efficacy.

108.5.1... Adverse Effects.

St. John's wort is generally well tolerated. Allergic skin reactions may occur, especially in people allergic to ragweed and daisies. In addition, the herb may cause CNS effects (eg, insomnia, vivid dreams, restlessness, anxiety, agitation, and irritability) as well as GI discomfort, fatigue, dry mouth, and headache. High-dose therapy may pose a risk of phototoxicity. To reduce this risk, light-skinned patients should minimize exposure to sunlight, wear protective clothing, and apply a sunscreen to exposed skin.

108.5.1... Interactions with Conventional Drugs.

St. John's wort is known to interact adversely with many drugs—and the list continues to grow. Three mechanisms are involved: induction of cytochrome P450 enzymes, induction of P-glycoprotein, and intensification of serotonin effects. Let's consider these one by one:

- *Induction of cytochrome P450* can accelerate the metabolism of many drugs, thereby decreasing their effects. This mechanism appears responsible for breakthrough bleeding and unintended pregnancy in women taking oral contraceptives, transplant rejection in patients taking cyclosporine (an immunosuppressant), reduced anticoagulation in patients taking warfarin, and reduced antiretroviral effects in patients taking protease inhibitors or non-nucleoside reverse transcriptase inhibitors.
- *P-glycoprotein* is a transport protein found in cells that line the intestine and renal tubules. In the intestine, P-glycoprotein transports drugs out of cells into the intestinal lumen; in renal tubules, P-glycoprotein transports drugs *out* of tubular cells into the urine. Hence, by increasing P-glycoprotein synthesis, St. John's wort can accelerate elimination of drugs, and can thereby reduce their effects. This is the mechanism by which St. John's wort greatly reduces levels of *digoxin*, a drug for heart failure. Other drugs whose levels can probably be reduced by this mechanism include calcium channel blockers, steroid hormones, protease inhibitors, and certain anticancer drugs (eg, etoposide, paclitaxel, vinblastine, vincristine).
- Combining St. John's wort with certain drugs can intensify serotonergic transmission to a degree sufficient to cause potentially fatal *serotonin syndrome*. Although St. John's wort can enhance serotonergic transmission by itself, its effect is relatively weak. Hence, when used alone, the herb poses little risk. However, if St. John's wort is combined with other serotonin-enhancing agents, the risk is greatly increased, and hence St. John's wort

should not be combined with such drugs. Among these are amphetamine, cocaine, and many antidepressants, including MAO inhibitors, selective serotonin reuptake inhibitors, certain tricyclic agents (e.g., amitriptyline, clomipramine), and duloxetine, nefazodone, and venlafaxine.

1270

Because St. John's wort has a variety of known adverse interactions—and is likely to have more that are as yet unknown—caution is clearly advised. St. John's wort is not recommended for treating depression in patients taking other medications.

1271

108.... Valerian

108.5.1... Uses.

Valerian root (*Valeriana officinalis*) is a sedative preparation used primarily to promote sleep. In addition, some people take it to reduce anxiety-associated restlessness.

108.5.1... Actions.

Valerian may work by increasing the availability of gamma-aminobutyric acid (GABA, an inhibitory neurotransmitter) at synapses in the CNS. (Benzodiazepines, which are the major conventional hypnotics, act by potentiating the actions of GABA.) In addition, valerian may act as a direct GABA agonist. The active ingredient(s) in valerian has not been identified.

108.5.1... Effectiveness.

Although valerian has been used for centuries in Europe, China, and other countries, objective evidence of efficacy is limited. In most studies to date, valerian reduced the time to sleep onset, and may have improved sleep quality. Effects develop slowly, over a period of days to weeks. In contrast, benzodiazepines work the first night they are taken. Evidence for reduction of anxiety-induced restlessness is limited.

108.5.1... Adverse Effects.

Valerian is generally very well tolerated. The FDA has given valerian a Generally Recognized as Safe (GRAS) rating when the product is consumed in amounts commonly used in food. Possible side effects include daytime drowsiness, dizziness, depression, dyspepsia, and pruritus. Prolonged use may cause headache, nervousness, or cardiac abnormalities. Because valerian can reduce alertness, users should exercise caution when performing dangerous activities, such as driving or operating dangerous machinery. In addition, valerian should be used with caution by people with psychiatric illnesses (eg, depression, dementia). As with benzodiazepines, there may be a risk of paradoxical excitation and physical dependence. We

do not know if valerian enters breast milk or harms the developing fetus. Until more is known, valerian should be avoided by women who are pregnant or breast-feeding.

108.5.1... Interactions with Conventional Drugs.

In theory, valerian can potentiate the actions of other drugs with CNSdepressant actions. Among these are alcohol, benzodiazepines, barbiturates, opioids, antihistamines, and centrally acting skeletal muscle relaxants. These combinations should be used with caution.

108.5.1... Comments.

Valerian was used as a tranquilizer throughout World War II and was listed in the U.S. Pharmacopeia prior to 1945. It was removed from the National Formulary following the introduction of more effective sedatives.

10... HARMFUL SUPPLEMENTS TO AVOID

To help protect the public from dangerous botanical products, the FDA and the Federal Trade Commission are monitoring adverse event data, and issuing warnings to consumers and manufacturers. Three potentially harmful products—comfrey, kava, and Ma huang—are discussed below.

108.6.1 Comfrey

Comfrey (*Symphytum officinale*) is a medicinal herb used topically and orally. Topical use appears safe. Oral use is not. Why? Because comfrey contains pyrrolizidine alkaloids, which can cause veno-occlusive disease (VOD) in animals and hepatic VOD in humans. Hepatic VOD can result in severe liver damage. In addition to causing VOD, pyrrolizidine alkaloids may also be carcinogenic. Accordingly, in July of 2001, the FDA issued a letter to dietary supplement manufacturers advising them to remove comfrey from the market. They urged manufacturers to discontinue production, pull existing product off the shelves, and warn consumers of the possible dangers.

108.6.2 Kava

Kava (*Piper methysticum*), also known as *kava-kava* or *awa*, is used to relieve anxiety, promote sleep, and relax muscles. In the United States, the herb has been promoted as a natural alternative to benzodiazepines (eg, diazepam [Valium]) for treating anxiety and stress. Unfortunately, kava can cause severe liver injury, leading the FDA to issue a public warning in March 2002. Later that year, the Centers for Disease Control and Prevention issued a report on kava-related hepatotoxicity. In the report, they discussed 11 cases of hepatotoxicity from the United States

and Europe in which the victims required a liver transplant owing to severe liver failure. Because of concerns over hepatotoxicity, kava sales have been restricted in Germany, Canada, Switzerland, France, and Australia—but not yet in the United States. For more information on kava, refer to the sixth edition of this book.

108.6.3 Ma Huang (Ephedra)

Ma huang (ephedra) contains ephedrine, a compound that can elevate blood pressure and stimulate the heart and CNS. High-dose ephedra has been associated with stroke, myocardial infarction, and death. To date, over 17,000 adverse events have been reported, and at least 155 users have died. In 2004, the FDA banned U.S. sales of all ephedra products, marking the first time that a dietary supplement has been ordered off the market. The ban was challenged by an ephedra producer and, in 2005, was partially reversed: A federal court upheld the ban for ephedra products that contain more than 10 mg/dose, but reversed the ban for products that contain 10 mg or less, arguing that there are insufficient data to prove that low doses pose a “significant or unreasonable risk.” In 2006, a federal appeals court upheld the FDA ban of ephedra. This ban was challenged again in 2007, but the U.S. Court of Appeals denied the petition for rehearing. At this time, the FDA ban does not apply to ephedra in traditional Asian medicines, which are not marketed as dietary supplements. For more information on Ma huang, refer to the sixth edition of this book.

1271

1272

108.6.3.1

KEY POINTS

- Dietary supplements can be defined as “vitamins, minerals, herbs or other botanicals, amino acids, and substances such as enzymes, organ tissues, glandulars, and metabolites” intended to promote health and relieve symptoms of disease.
- Dietary supplements are regulated under the Dietary Supplement Health and Education Act of 1994 (DSHEA) and the Current Good Manufacturing Practices (CGMPs) ruling issued in 2007.
- Unlike conventional drugs, dietary supplements can be marketed without any proof of safety or efficacy.
- Under the DSHEA, dietary supplements are presumed safe until proved harmful. Hence, manufacturers don't have to prove their products are safe. Rather, the FDA has to prove they're not.

- Manufacturers can claim that a product favorably influences “body structure and function,” but cannot claim that it can be used to diagnose, treat, cure, or prevent any disease.
- Dietary supplements can interact with conventional drugs, sometimes with serious results. Be sure to ask patients if they are using medicinal herbs or other dietary supplements.
- The word *natural* is not synonymous with *safe*. Remember, poison ivy and tobacco are natural too.

¹⁰⁹CHAPTER 108 Management of Poisoning

Poisoning is defined as a pathologic state caused by a toxic agent. Sources of poisoning include medications, plants, environmental pollutants, and drugs of abuse. These toxicants may enter the body orally or by inhalation, injection, or absorption through the skin. Poisoning may be unintentional (accidental) or intentional. Symptoms of poisoning often mimic those of disease, and hence the possibility of poisoning should be considered whenever a diagnosis is made.

In the United States, over 2 million poisonings are reported annually. In 2005, accidental poisoning caused 23,618 deaths, and intentional poisoning caused 5833 more. Most poisoning deaths are caused by drugs: In 2004, 95% of deaths from accidental poisoning were caused by drugs, as were 75% of suicides. The *incidence* of poisoning is highest in young children. However, the *mortality rate* in this group is very low. In 2000, poisoning-related medical expenses were \$26 billion.

^{10...}FUNDAMENTALS OF TREATMENT

Poisoning is a medical emergency and requires rapid treatment. Management has five basic elements: (1) supportive care, (2) identification of the poison, (3) prevention of further absorption, (4) poison removal, and (5) use of specific antidotes. These essentials are discussed below.

^{109.1.1}Supportive Care

Supportive care is the most important element in managing acute poisoning. Support is based on the clinical status and requires no knowledge specific to the poison involved. Maintenance of respiration and circulation are primary concerns. Measures for respiratory support include inserting an airway, giving humidified oxygen, and providing mechanical ventilation. Volume depletion (resulting from vomiting, diarrhea, or sweating) can compromise circulation. Volume should be restored by administering normal saline or Ringer's solution. Severe hypoglycemia may occur, resulting in coma. Levels of blood glucose should be monitored. For coma of unknown etiology, IV dextrose should be given immediately—even if information on blood glucose is lacking. Acid-base disturbances may occur; determination of arterial blood gases will facilitate diagnosis and management. If convulsions develop, IV diazepam is the treatment of choice.

^{109.1.2}Poison Identification

Treatment of poisoning is facilitated by knowing the identity and dosage of the toxicant. Efforts to obtain this information should proceed concurrently with medical management.

A history is one way to identify the toxic agent. However, experience has shown that histories taken at times of poisoning are often inaccurate. Hence, statements about the nature or quantity of poison may not be correct.

Positive identification can be made using analytic techniques. A gas chromatograph/mass spectrometer can provide qualitative and quantitative information. Analyses can be performed on specimens of urine, blood, and gastric contents. To determine whether poison levels are rising or falling, analyses should be performed on sequential blood samples taken about 2 hours apart.

109.1.3 Prevention of Further Absorption

By reducing the absorption of a poison, we can minimize blood levels, and thereby significantly decrease morbidity and mortality. For ingested poisons, five procedures are available: (1) giving activated charcoal, (2) inducing emesis with syrup of ipecac, (3) gastric lavage and aspiration, (4) whole-bowel irrigation, and (5) catharsis. When poison exposure is topical, surface decontamination is employed. Details of these procedures are discussed in the following section.

109.1.4 Promotion of Poison Removal

Measures that help eliminate poison from the body shorten the duration of exposure and, if implemented before plasma levels have peaked, can reduce the maximum level of poison achieved. By shortening exposure and reducing maximum poison levels, these measures can decrease morbidity and mortality.

Removal of poison can be promoted with drugs and with nonpharmacologic techniques. The drugs used for poison removal act by increasing renal excretion of toxic agents. Nonpharmacologic methods of poison removal include peritoneal dialysis, hemodialysis, and exchange transfusion. Details on methods of poison removal are presented later.

109.1.5 Use of Specific Antidotes

An antidote is an agent administered to counteract the effects of a poison. Examples include naloxone (to reverse poisoning by heroin and other opioids) and physostigmine (to treat poisoning by atropine and other anticholinergic drugs). Several specific antidotes are discussed later. Unfortunately, although antidotes can be extremely valuable, these agents are rare: For most poisons, no specific antidote exists. Hence, for most patients, treatment is limited to the general measures described above.

1273

1274

^{10...} DRUGS AND PROCEDURES USED TO MINIMIZE POISON ABSORPTION

^{109.2.1} Reducing Absorption of Ingested Poisons

^{109.2.1.1} Activated Charcoal

Treatment with activated charcoal is a preferred method for removing ingested poisons from the GI tract. Activated charcoal is an inert substance that adsorbs drugs and other chemicals. Binding of toxicants to charcoal is essentially irreversible. Because charcoal particles cannot be absorbed into the blood, adsorption of poisons onto charcoal prevents toxicity. The charcoal-poison complex is eliminated in the stool. Patients should be advised that charcoal will turn the feces black. Charcoal is very safe, but should not be used in patients with bowel perforation or obstruction.

Charcoal selectively adsorbs *large molecules* that contain a *carbon atom*. Adsorption of small molecules and molecules that lack a carbon atom is poor. Among these poorly absorbed molecules are heavy metals, caustics and corrosives, alcohols and glycols, chlorine, iodine, and petroleum distillates.

Because charcoal can adsorb antidotes, and thereby neutralize their benefits, antidotes should not be administered immediately before, with, or shortly after the charcoal.

Activated charcoal has the consistency of a fine powder and is mixed with water for oral administration. The adult dose is 60 to 100 gm. Pediatric doses range from 15 to 30 gm. For poisoning with certain compounds—phenobarbital, dapsone, quinidine, theophylline, and carbamazepine—giving sequential doses of charcoal can be beneficial. When administered within 30 minutes after poison ingestion, charcoal can adsorb about 90% of the dose. However, if given 60 minutes after poison ingestion, the amount adsorbed decreases to only 37%.

Clearly, charcoal should be given as soon as possible after poison exposure.

^{109.2.1.2} Syrup of Ipecac

^{109.2.1.2.1} Actions and Uses.

Syrup of ipecac induces vomiting, and can thereby help remove ingested poison from the stomach. Ipecac promotes emesis by stimulating the chemoreceptor trigger zone of the medulla and by irritating the stomach. Vomiting usually occurs 20 to 30 minutes after administration. The drug's most common side effects are sedation and diarrhea.

Unfortunately, ipecac is not very effective: It removes only 30% of ingested poison, even when given early (within 30 minutes of poison ingestion). Furthermore, when administered at home to children younger than 6 years, ipecac does not reduce the need for emergency department use, and it does not improve health outcomes.

109.2.1.2.2 Guidelines for Ipecac Use.

Although induction of vomiting was common in the past, it is rarely done today. Between 1985 and 1995, ipecac use in cases of poisoning dropped from 15% to only 2.3%, and usage is even lower today. The American Academy of Clinical Toxicology has issued the following guidelines on ipecac use:

- Ipecac should not be used routinely.
- Routine use in the emergency department should be abandoned.
- Ipecac should not be given to patients with seizures or a reduced level of consciousness, or to patients who cannot protect their airways (eg, those lacking a gag reflex).
- Ipecac should not be administered after ingestion of (1) corrosive acids or bases, (2) hydrocarbons with a high potential for aspiration, (3) substances that could cause a rapid loss of consciousness, and (4) substances that could cause seizures requiring advanced life support within 60 minutes.
- When ipecac is used, it should be given within 60 minutes of poison ingestion, and only to patients who are alert, conscious, and have ingested a potentially toxic dose.

Consistent with these recommendations, in 2003, the American Academy of Pediatrics (AAP) withdrew its long-standing recommendation that parents keep a bottle of ipecac syrup in the home. Instead, the AAP now recommends *against* routine home use of ipecac, and urges parents to discard any ipecac they may have.

109.2.1.2.3 Preparations, Dosage, and Administration.

Ipecac syrup is supplied in 15- and 30-mL containers. Currently, the drug is available without prescription. Fluid in the stomach increases the effects of ipecac. Hence, administration should be accompanied by an appropriate volume of water. Dosage is a function of age:

- *Children less than 6 months old*—use only under a physician's supervision

- *Children 6 to 12 months old*—5 to 10 mL followed by 120 to 240 mL of water
- *Children 1 to 12 years old*—15 mL followed by 120 to 240 mL of water
- *Individuals over 12 years old*—15 to 30 mL followed by 240 mL of water

If vomiting does not occur within 20 minutes, dosing can be repeated.

109.2.1.3 Gastric Lavage and Aspiration

Gastric lavage (irrigation) and aspiration consists of flushing the stomach with fluid and then sucking (aspirating) the fluid back out. The procedure should be done only in life-threatening cases, and only if less than 60 minutes has elapsed since poison ingestion. Specific contraindications to lavage and aspiration include

- Ingestion of caustic agents (owing to the risk of esophageal perforation)
- Convulsions (owing to the risk of injury from the procedure, including aspiration of stomach contents into the lungs)
- Ingestion of high-viscosity petroleum distillates
- Significant cardiac dysrhythmias
- Emesis of blood

Lavage and aspiration is accomplished using a large-bore orogastric tube (No. 36 to 42 French for adults, No. 22 to 28 French for children). Smaller tubes should be avoided because they may not permit removal of solids (food, pills, capsules, tablets) and because their small diameter would impede flow of the lavage fluid. If the patient is comatose, an endotracheal tube with an inflatable cuff should be installed to protect the airway. Because of the anatomy of the stomach, the patient should be placed on the left side with the head down. Prior to initiation of lavage, stomach contents should be aspirated and sent for toxicologic analysis. Lavage may be performed employing tap water or saline solution. Multiple washes are instilled using 150 to 200 mL/wash (for adults and older children) or 50 to 100 mL/wash (for children under 5 years old). Larger volumes should be avoided since they may push stomach contents into the small intestine. Washes should be repeated until the fluid retrieved from the stomach is clear. About 10 to 12 washes are employed.

109.2.1.4 Whole-Bowel Irrigation

Whole-bowel irrigation is done with a solution of polyethylene glycol that contains balanced electrolytes, available under the trade names CoLyte and GoLYTELY. The solution is administered repeatedly over a 5-hour period, either by mouth or through a nasogastric tube. Rates of administration are as follows:

- For patients 12 years old—1.5 to 2 L/hr
- For patients 6 to 12 years old—1 L/hr
- For patients less than 6 years old—0.5 L/hr

The procedure has been effective following ingestion of iron, lithium, and lead, as well as sustained-release products. Whole-bowel irrigation should not be used in patients with ileus, peritonitis, bloody vomitus, or obstruction or perforation of the bowel.

109.2.1.5 Catharsis

Cathartics can hasten passage of toxicants through the intestine and, in theory, may thereby minimize absorption. However, there are no data to prove that cathartics improve clinical outcome. Hence, although these agents were used widely in the past, they are not recommended today.

1274

109.2.2 Surface Decontamination

1275

Topical exposure to toxicants can cause local and systemic injury. To minimize injury, contaminated clothing should be removed, and the poison should be washed from the victim. The recommended procedure is to alternate soap-and-water washes with alcohol washes. Personnel performing these washes should take precautions to avoid contaminating themselves. If the victim's eyes have been exposed, they should be flushed with water for at least 15 minutes. Shampoo should be employed to remove toxic agents from the hair and scalp.

10... DRUGS AND PROCEDURES USED FOR POISON REMOVAL

109.3.1 Drugs That Enhance Renal Excretion

Drugs that alter the pH of urine can accelerate the excretion of organic acids and bases. Agents that *elevate* urinary pH (ie, make the urine more alkaline) will promote the excretion of *acids*. Drugs that *lower* urinary pH will promote the excretion of *bases*. The mechanism underlying these effects is called *ion trapping* (see [Chapter 4](#)).

The drugs employed most frequently to alter urinary pH are *sodium bicarbonate* and *ammonium chloride*. Both are administered IV. Sodium bicarbonate renders the urine more alkaline, which decreases the passive reabsorption of acids (eg, aspirin, phenobarbital), and thereby accelerates their excretion. Ammonium chloride acidifies the urine, and thereby increases the excretion of bases (eg, amphetamines, phencyclidine). Because of the buffer systems present in blood, sodium bicarbonate and ammonium chloride have a relatively small effect on the pH of blood, while having a large effect on the pH of urine.

^{109.3.2} Nondrug Methods of Poison Removal

Several nondrug procedures—peritoneal dialysis, hemodialysis, hemoperfusion, and exchange transfusion—can be employed to remove toxicants from the body. Although these procedures are usually of limited value, they can be lifesaving in some situations. Nondrug procedures are most effective when (1) binding of toxicants to plasma proteins is low, and (2) blood levels of toxicants are high (ie, when distribution of the toxic agent is restricted to the blood and extracellular fluid).

Each of the nondrug methods of poison removal has its benefits and drawbacks. *Peritoneal dialysis* has two advantages: the procedure is relatively simple and it occupies a minimum of staff time. *Hemodialysis*, although more difficult than peritoneal dialysis, is about 20 times more effective. *Hemoperfusion* is a process in which blood is passed over a column of charcoal or absorbent resin. If the affinity of the resin for a particular poison is high, the procedure can strip a toxicant from binding sites on plasma proteins. The principal disadvantage of hemoperfusion is loss of platelets. When binding of a poison to plasma proteins is particularly avid, *exchange transfusion* can be an effective method of removal.

^{10...} SPECIFIC ANTIDOTES

^{109.4.1} Heavy Metal Antagonists

The heavy metals most frequently responsible for poisoning are iron, lead, mercury, arsenic, gold, and copper. These metals cause injury by forming complexes with enzymes and other physiologically important molecules. Poisoning may result from environmental exposure, intentional overdose, or therapeutic use of heavy metals.

The drugs given to treat heavy metal poisoning are called *chelating agents* or *chelators*. These agents interact with metals to form *chelates*—ring structures in which the metal and the chelating agent form two or more points of attachment. The chelate formed by mercury and dimercaprol illustrates this concept ([Fig. 108-1](#)).

Useful chelating agents have a high affinity for heavy metals, and hence can compete successfully with endogenous molecules for metal binding. By preventing initial binding of metals to endogenous molecules, chelators can prevent injury. By stripping metals that have already become bound, chelators can enhance their excretion.

The selectivity of a heavy metal antagonist is determined by its affinity for specific metals. Some antagonists are selective for only one metal; others can form chelates with several metals. Deferoxamine, for example, binds selectively to iron. In contrast, dimercaprol is relatively nonselective, binding tightly with arsenic, mercury salts, and gold.

Properties desirable in a heavy metal antagonist include (1) high affinity for a toxic metal, (2) low affinity for essential endogenous metals (eg, magnesium, zinc), (3) the ability to reach sites of metal storage, (4) high activity at physiologic pH, (5) formation of chelates that are less toxic than the free metal, and (6) formation of chelates that are easily excreted.

109.4.1.1 Deferoxamine

109.4.1.1.1 Actions and Uses.

Deferoxamine [Desferal] has a high affinity for ferric iron. The drug chelates free iron and can also strip iron bound to ferritin and hemosiderin. In contrast, iron present in hemoglobin and cytochromes is not affected. Deferoxamine is employed to treat acute and chronic iron toxicity.

109.4.1.1.2 Pharmacokinetics.

Deferoxamine is poorly absorbed from the GI tract, and hence administration is parenteral. The chelate formed between deferoxamine and iron is excreted primarily in the urine.

109.4.1.1.3 Adverse Effects.

Common reactions include fever (23.8%), headache (20.3%), cough (19%), pharyngolaryngeal pain (14.8%), nasopharyngitis (14.5%), and bronchitis (11%). Pain may occur at the site of injection. Rapid IV infusion may cause hypotension, tachycardia, erythema, and urticaria. Prolonged therapy may be associated with allergic reactions, abdominal discomfort, leg cramps, fever, and dysuria.

109.4.1.1.4 Contraindications.

Because deferoxamine is excreted by the kidneys, the drug should not be given to patients with renal insufficiency. Deferoxamine has caused fetal malformations in experimental animals, and hence is not recommended for pregnant women.

109.4.1.1.5 Preparations, Dosage, and Administration.

Deferoxamine mesylate [Desferal] is supplied as a powder to be reconstituted for injection. The drug can be administered by IM injection and by IV or subQ infusion. Intramuscular injection is preferred. Intravenous infusion is usually reserved for patients in shock. The dosage for IM or IV administration is the same. The initial dose for adults and children is 1 gm. This is followed 4 and 8 hours later with 0.5-gm doses. For IV administration, the maximum rate of infusion is 15 mg/kg/hr. For patients with iron overload associated with chronic blood infusions (see discussion of deferasirox below), the dosage is 20 to 40 mg/kg/day, administered by a prolonged (8- to 12-hr) subQ infusion.

Figure 108-1 Chelation of mercury by dimercaprol.

109.4.1.2 Deferasirox

109.4.1.2.1 Actions and Uses.

Deferasirox [Exjade] is an important new drug for oral therapy of iron overload resulting from chronic blood transfusions in patients with beta-thalassemia, sickle cell anemia, and other disorders. Left untreated, iron overload can injure the liver, heart, and other organs. Cardiac injury is of special concern owing to a risk of dysrhythmias, heart failure, and even death. Deferasirox is a chelating agent with a high affinity for iron, and much lower affinity for zinc and copper.

Compared with deferoxamine, the only other drug for infusion-related iron overload, deferasirox is a welcome option. Why? Because dosing is much easier: Deferasirox is taken orally, whereas deferoxamine requires parenteral administration, usually by prolonged (8- to 12-hour) sub Q infusions done 5 to 7 nights a week.

109.4.1.2.2 Pharmacokinetics.

Administration is oral, and plasma levels peak 1.4 to 4 hours after dosing. In the blood, deferasirox is highly bound to albumin. The drug undergoes hepatic metabolism followed by excretion in the bile. Deferasirox and its metabolites are then eliminated mainly (84%) in the feces. The plasma half-life is 8 to 16 hours.

109.4.1.2.3 Adverse Effects.

The most common effects are fever (18.9%), headache (15.9%), cough (13.9%), nasopharyngitis (13.2%), and GI reactions, including abdominal pain (13.9%), nausea (10.5%), vomiting (10.1%), and diarrhea (11.8%). Renal damage, indicated by a rise in plasma creatinine, is seen in 11.1% of patients. Some patients (less than 1%) experience hearing loss and ocular disturbances, and hence hearing and vision tests should be done before treatment and every 12 months thereafter.

109.4.1.2.4 Preparations, Dosage, and Administration.

Deferasirox [Exjade] is supplied in tablets (125, 250, and 500 mg) that must be dispersed in fluid (water, orange juice, apple juice) before dosing. The tablets should not be swallowed whole. For doses of less than 1 gm, disperse tablets in 3.5 ounces of fluid; for doses greater than 1 gm, disperse in 7 ounces. Dosing is done once a day on an empty stomach (ie, at least 30 minutes before eating), at the same time each day. The drug must not be taken with aluminum-containing antacids.

The starting dosage is 20 mg/kg/day. Dosage can be adjusted every 3 to 6 months based on serum ferritin levels, but must not exceed 30 mg/kg/day. If serum ferritin falls consistently below 500 mcg/L, temporary interruption of treatment should be considered. Dosage should be reduced if renal function declines.

109.4.1.3 Dimercaprol

109.4.1.3.1 Actions and Uses.

Dimercaprol [BAL In Oil] binds with arsenic, gold, and mercury. The resulting chelates are excreted in the urine. The drug is used as the sole chelator to rid the body of arsenic, mercury, or gold. In addition, dimercaprol can be combined with edetate calcium disodium (calcium EDTA) to treat poisoning with lead. Since dimercaprol is more effective at *preventing* binding of metals to endogenous molecules than at reversing binding that has already taken place, benefits are greatest when the drug is administered early (within 1 to 2 hours of metal ingestion).

109.4.1.3.2 Pharmacokinetics.

Administration is by deep IM injection. Dimercaprol cannot be used orally. The drug has a short plasma half-life (complete elimination occurs in approximately 4 hours).

109.4.1.3.3 Adverse Effects.

At recommended doses, dimercaprol is generally well tolerated. Tachycardia and elevation of blood pressure occur frequently; blood pressure returns to baseline within hours. Pain and sterile abscesses may occur at sites of injection. Fever is common in children. High doses produce a broad spectrum of untoward effects.

Chelates formed with dimercaprol are unstable at acidic pH. Hence, if the urine is acidic, heavy metals may dissociate from dimercaprol, resulting in renal toxicity. To protect the kidneys, the urine should be kept alkaline.

Dimercaprol is formulated in peanut oil, and hence should be avoided by patients with known or suspected peanut allergy.

109.4.1.3.4 Preparations, Dosage, and Administration.

Dimercaprol [BAL In Oil] is supplied in ampules containing 300 mg of the drug in 3 mL of peanut oil. The preparation is administered by deep IM injection. For *mild poisoning with gold or arsenic*, doses of 2.5 mg/kg are administered according to the following schedule: 4 times daily on days 1 and 2, twice daily on day 3, and once daily on days 4 through 13. For *acute poisoning with mercury*, the initial dose is 5 mg/kg. Subsequent doses of 2.5 mg/kg are administered 1 or 2 times daily for 10 days.

109.4.1.4 Edetate Calcium Disodium (Calcium EDTA)

109.4.1.4.1 Actions and Uses.

Calcium EDTA [Calcium Disodium Versenate] is used primarily for lead poisoning. The drug combines with lead to form a stable chelate that is excreted in the urine.

109.4.1.4.2 Pharmacokinetics.

Calcium EDTA may be administered IV or IM. The drug is poorly absorbed from the GI tract, and hence is not given orally. Elimination is by glomerular filtration. Because calcium EDTA is excreted by the kidneys, the drug should be employed only if urine flow is adequate. If urine flow is insufficient, flow should be restored with IV fluids prior to giving the chelator. If anuria develops during the course of treatment, administration should stop.

109.4.1.4.3 Adverse Effects.

The principal toxicity of calcium EDTA is renal tubular necrosis. Signs include hematuria and proteinuria. Daily urinalysis should be performed to monitor for these effects. If renal toxicity develops, the drug should be discontinued immediately.

109.4.1.4.4 Preparations, Dosage, and Administration.

Calcium EDTA [Calcium Disodium Versenate] is supplied in 5-mL ampules containing 1000 mg of drug. Administration may be IV or IM. The IV route is preferred for adults, whereas IM is preferred for children.

For IV use, the contents of 1 ampule are diluted in 250 to 500 mL of 5% dextrose solution or normal saline. Infusion should be done slowly (over 1 hour or more). The adult dosage is 1 gm twice daily for 5 days. After a 2-day hiatus, a second course may be given if needed.

The IM dosage for children is 35 mg/kg (or less) administered twice daily for 3 to 5 days. After a pause of 4 days or longer, a second course is given.

109.4.1.5 Penicillamine

109.4.1.5.1 Actions.

Penicillamine [Cuprimine, Depen] is a breakdown product of penicillin. Commercial preparations are made synthetically. Penicillamine forms water-soluble chelates with copper, iron, lead, arsenic, gold, and mercury. These complexes are excreted in the urine.

109.4.1.5.2 Therapeutic Uses.

The principal indication is *Wilson's disease*, a disorder of copper metabolism. Individuals with the disease are deficient in ceruloplasmin, a plasma protein that serves as a copper carrier. Symptoms result from deposition of copper in the liver, brain, kidneys, eyes, and other organs. Penicillamine relieves symptoms by promoting copper excretion. Therapeutic effects may take several months to develop. Additional uses are *rheumatoid arthritis* and *cystinuria*. Beneficial effects in these disorders are not related to chelation of heavy metals.

109.4.1.5.3 Pharmacokinetics.

Penicillamine is well absorbed following oral administration. Food greatly reduces the extent of absorption. Once absorbed, penicillamine is rapidly excreted in the urine.

109.4.1.5.4 Adverse Effects.

With prolonged use, penicillamine can cause varied and serious toxicities. Deaths have occurred. The drug should be employed only with close medical supervision. Possible cutaneous reactions include urticaria, maculopapular and morbilliform rash, pemphigoid lesions, and pruritus. Bone marrow suppression can result in leukopenia, agranulocytosis, and aplastic anemia, all of which can be fatal. Autoimmune and immune complex disorders have been associated with penicillamine. Among these are dermatomyositis, polymyositis, lupus erythematosus, alveolitis, and myasthenia gravis. Renal toxicity may occur.

109.4.1.5.5 Contraindications.

Penicillamine is contraindicated for patients who have experienced agranulocytosis or aplastic anemia when receiving penicillamine in the past. The drug is also contraindicated for patients with rheumatoid arthritis who are pregnant or have renal insufficiency.

109.4.1.5.6 Preparations, Dosage, and Administration.

Penicillamine [Cuprimine, Depen] is supplied in 125-mg capsules and 250-mg tablets. For *Wilson's disease*, the usual dosage is 250 mg 4 times a day. Doses should be administered 1 hour before meals and at bedtime. Dosage is adjusted on the basis of untoward effects and urinary copper content. Treatment is long term.

109.4.1.6 Succimer

109.4.1.6.1 Actions and Uses.

Succimer [Chemet] binds avidly with lead, mercury, and arsenic. Binding is less avid with copper and zinc. Binding to iron, calcium, and magnesium is minimal, and therefore succimer presents no risk of depleting these essential minerals. Succimer is our most effective drug for lowering blood levels of lead in children, its only approved indication. However, although succimer can reduce lead levels, benefits are limited to prevention of seizures and death from acute encephalopathy. Treatment does not reduce or prevent the long-term neurologic sequelae of lead poisoning, which are irreversible.

109.4.1.6.2 Pharmacokinetics.

Succimer is rapidly but variably absorbed following oral administration. The drug undergoes extensive metabolism. Metabolites and parent drug are eliminated slowly in the urine.

109.4.1.6.3 Adverse Effects.

Adverse effects appear to be mild. About 10% of patients experience GI reactions (nausea, diarrhea, cramps). Other moderate reactions include nasal congestion, muscle pain, and rash. Succimer has caused temporary elevations in serum transaminases, indicating liver injury. Accordingly, serum transaminases should be measured before treatment and weekly thereafter. In addition, caution should be exercised in patients with liver disease. In mice, the drug is teratogenic and fetotoxic.

1276

109.4.1.6.4 Preparations, Dosage, and Administration.

1277

Succimer [Chemet] is supplied in 100-mg capsules for oral use. For children over 1 year old, treatment consists of 10 mg/kg or 350 mg/m² every 8 hours for 5 days, and then every 12 hours for 14 more days. If needed, the entire course can be repeated after a minimum hiatus of 2 weeks.

109.4.2 Fomepizole

109.4.2.1 Actions and Uses.

Fomepizole [Antizole] is used to treat poisoning by *ethylene glycol*, the principal component of antifreeze. Following ingestion, ethylene glycol undergoes gradual enzymatic conversion into glycolic acid, a toxic acidic metabolite. The result is profound metabolic acidosis, which leads

to hyperventilation, coma, seizures, hypertension, pulmonary infiltrates, and renal failure. In the absence of treatment, a lethal dose (100 mL or more) will cause death by multiorgan failure in 24 to 36 hours. Fomepizole protects against injury by inhibiting *alcohol dehydrogenase*, an enzyme required for conversion of ethylene glycol into its toxic form.

In addition to receiving fomepizole, patients need treatment for metabolic acidosis, acute renal failure, hypocalcemia, and adult respiratory distress syndrome. Treatment options include fluids, sodium bicarbonate, potassium, calcium, and oxygen. If poisoning is severe, patients may require hemodialysis.

109.4.2.2 Pharmacokinetics.

After IV infusion, fomepizole distributes rapidly throughout total body water. A plasma level of 8.2 to 24.6 mg/L is sufficient to inhibit alcohol dehydrogenase. Fomepizole undergoes hepatic metabolism followed by excretion in the urine. The drug induces hepatic P450 enzymes, and can thereby accelerate its own metabolism. With repeated dosing, a significant increase in metabolism can be seen 30 to 40 hours after the initial dose.

109.4.2.3 Adverse Effects.

Fomepizole is well tolerated. The only common adverse effects are headache (12%), nausea (11%), and dizziness (7%). All other adverse effects (eg, bradycardia, seizures) are uncommon.

109.4.2.4 Preparations, Dosage, and Administration.

Fomepizole [Antizole] is available as a concentrated solution (1 gm/mL) in 1.5-mL vials. The required dose should be withdrawn from the vial and diluted in at least 100 mL of 0.9% sterile saline or 5% dextrose. Treatment consists of a loading dose (15 mg/kg) followed by four smaller doses (10 mg/kg) given every 12 hours, followed in turn by doses of 15 mg/kg given every 12 hours until ethylene glycol levels drop below 20 mg/dL. All doses are infused IV over 30 minutes. If the patient is undergoing hemodialysis, fomepizole must be given every 4 hours, rather than every 12.

109.4.3 Other Important Antidotes

Throughout this text we discussed the toxic effects of various drugs. Where appropriate, we discussed specific antidotes used for treatment. For example, when discussing the adverse effects of opioids, we also discussed use of naloxone for opioid overdose. Similarly, when discussing heparin toxicity, we discussed the use of protamine sulfate as treatment. The major specific antidotes presented in other chapters are summarized in [Table 108-1](#).

^{10...} POISON CONTROL CENTERS

The American Association of Poison Control Centers (AAPCC) defines a poison center as an organization that serves a designated geographic region and provides the following services:

- Poison information
- Telephone management advice and consultation about toxic exposures
- Hazard surveillance to achieve hazard elimination
- Professional and public education in poisoning prevention, diagnosis, and treatment

1277

TABLE 108-1 Specific Antidotes Discussed in Other Chapters

Antidote			
Generic Name	Trade Name	Toxic/Overdosed Substance	Chapter
Atropine		Muscarinic agonists, cholinesterase inhibitors	14
Physostigmine	Antilirium	Anticholinergic drugs	15
Neostigmine	Prostigmin	Nondepolarizing neuromuscular blockers	15
Pralidoxime	Protopam	Organophosphate cholinesterase inhibitors	15
Naloxone	Narcan	Opioids	28
Flumazenil	Romazicon	Benzodiazepines	34
Digoxin immune Fab	Digibind	Digoxin, digitoxin	47
Vitamin K		Warfarin	51
Protamine sulfate		Heparin	51
Glucagon		Insulin-induced hypoglycemia	56
Acetylcysteine	Mucomyst	Acetaminophen	70
Leucovorin	Wellcovorin	Methotrexate and other folate antagonists	101
Penetrate calcium trisodium		Radioactive plutonium, americium, or curium	109
Penetrate zinc trisodium		Radioactive plutonium, americium, or curium	109
Prussian blue	Radiogardase	Radioactive cesium-137 and nonradioactive thallium	109
Potassium iodide		Radioactive iodine	109

Poison centers certified by the AAPCC are accessible 24 hours a day; have a specially trained, full-time staff (usually nurses, pharmacists, or both); are directed by a board-certified physician-toxicologist; and are associated with a medical center that has laboratory facilities and personnel needed for the diagnosis and management of poisoning. These centers are accessible by phone and can provide immediate instruction on the management of acute poisoning. In the majority of cases, the information supplied will permit successful treatment at home. By facilitating rapid treatment, poison control centers can decrease morbidity and mortality, and can help reduce the cost of emergency care.

In 2002, the AAPCC established a **NATIONAL POISON HOTLINE: 1-800-222-1222** Dialing this number from any place in the United States will connect you with the *local* poison center. (This is like dialing 911 from any place in the country to contact local emergency-service providers.)

109.5.1

KEY POINTS

- Management of poisoning has five basic components: supportive care, poison identification, prevention of further absorption, promotion of poison removal, and use of specific antidotes.
- The preferred methods for reducing absorption of ingested poisons are adsorption onto activated charcoal and whole-bowel irrigation.
- Removal of absorbed poisons can be accelerated by using drugs to enhance renal excretion and by nondrug methods, such as hemodialysis and exchange transfusion.
- For most poisons there is no specific antidote.
- Heavy metal poisoning can be treated with chelating agents.
- Poison control centers offer immediate, expert assistance over the phone.
- Dialing 1-800-222-1222 from any place in the United States will connect you with the nearest poison control center.

¹¹⁰CHAPTER 109 Potential Weapons of Biologic, Radiologic, and Chemical Terrorism

In fall of 2001, the United States was hit by unprecedented terrorist attacks. On September 11, terrorists hijacked four commercial jets, and succeeded in crashing two into the twin towers of the World Trade Center and one into the Pentagon. In October, anthrax spores were mailed to several locations, causing illness and death. These events have generated great concern about our vulnerability to more such attacks, and our ability to manage the consequences.

To improve our readiness for a terrorist attack, the federal government created *Project BioShield* in 2004, and passed the *Pandemic and All-Hazards Preparedness Act* in 2007. Both incentives were designed to spur development and production of drugs and vaccines to protect U.S residents from bioterror agents, such as anthrax, smallpox, botulism, and plague. Although there have been some notable results, a great deal more needs to be done.

In this chapter, we discuss some of the potential weapons of terrorism, focusing primarily on bacteria and viruses. Biotoxins, chemicals (nerve agents and mustard gas), and radiologic weapons are addressed as well. Discussion centers on clinical manifestations and treatment. Prevention is addressed where appropriate.

For more information on the weapons discussed here, or for information on other potential weapons, you can consult the online resources listed in [Table 109-1](#).

11... BACTERIA AND VIRUSES

110.1.1 *Bacillus anthracis* (Anthrax)

Bacillus anthracis is the bacterium that causes anthrax, a disease with three major forms: inhalational, cutaneous, and gastrointestinal. Our discussion focuses on inhalational and cutaneous anthrax. Gastrointestinal anthrax is not addressed because this form is unlikely to result from a terrorist attack.

Of the microbes that might be used by terrorists, *Bacillus anthracis* is among the most dangerous. In October 2001, spores of *B. anthracis* were mailed to several locations in the United States, causing 22 confirmed or suspected cases of anthrax and 5 deaths. This experience served to heighten concerns regarding the feasibility of terrorist groups using aerosolized bioweapons to stage large-scale attacks.

110.1.1.1 Microbiology

Bacillus anthracis is an aerobic, gram-positive bacterium. Its name derives from *anthrakis*, the Greek word for coal (in recognition of the black skin lesions that characterize cutaneous infection). *Bacillus anthracis* can exist as spores (which are dormant) or as actively growing bacteria. Infection is acquired when the *spores* enter a host. Ports of entry are skin lesions and the respiratory and GI tracts. In the presence of nutrients (amino acids, nucleotides, glucose), which are abundant in the blood and tissues of the host, the spores germinate and transform into mature bacteria. The mature forms grow and divide rapidly until the nutrient supply is depleted, after which they cease dividing and produce more spores. The mature bacteria cannot survive long outside the host. In contrast, the spores can remain viable in the environment for decades. Anthrax is not transmitted person to person.

1279

1280

110.1.1.2 Clinical Manifestations

110.1.1.2.1 Inhalational Anthrax.

Infection begins with deposition of anthrax spores in the alveolar space, followed by transport to regional lymph nodes, where germination occurs. Clinical latency can range from 2 days to 6 weeks. Injury results when mature bacilli release toxins, which cause hemorrhage, edema, and necrosis. Once the concentration of toxin has reached a critical level, antibiotics cannot prevent death, even if they kill all circulating bacilli.

Symptoms appear in two stages. Initial symptoms—fever, cough, malaise, and weakness—may be relatively mild. In the second stage, which develops 2 to 3 days later, there is a sudden increase in fever, along with severe respiratory distress, septicemia, hemorrhagic meningitis, and shock. Interestingly, although the infection originates in the lungs, true pneumonia rarely occurs. Even with treatment, the mortality rate can be high: In the U.S. outbreak of 2001, 45% of victims died.

110.1.1.2.2 Cutaneous Anthrax.

Symptoms begin 1 to 7 days after exposure to anthrax spores. Areas with cuts or abrasions are most vulnerable, but injury can develop at any site where spores land. The initial lesion is a small papule (solid raised area) or vesicle (fluid-filled raised area) associated with localized itching. Within 2 days, the lesion enlarges and evolves into a painless ulcer with a necrotic core. Seven to 10 days after symptom onset, a black eschar (scab-like structure) forms—but then dries, loosens, and sloughs off by day 12 to 14. In most patients, the lesions resolve

without complications or scarring. However, if *systemic* infection develops, the outcome can be fatal. In the absence of antibiotic therapy, about 20% of people with cutaneous anthrax die. In contrast, death among treated patients is rare.

110.1.1.3 Treatment of Established Infection

The treatments discussed here reflect consensus-based recommendations published in *JAMA* in an article titled “Anthrax as a Biological Weapon, 2002: Updated Recommendations for Management.”

110.1.1.3.1 Inhalational Anthrax.

Given the rapid course that inhalational anthrax follows, early therapy with antibiotics is essential. Any delay can reduce the chance of survival. Initial IV therapy is preferred to initial oral therapy. However, if there are mass casualties, IV therapy may be impossible, owing to limited supplies and personnel. Ideally, treatment should start with IV *ciprofloxacin* or IV *doxycycline*. Because the strain of *B. anthracis* may be resistant to these drugs, one or two other IV antibiotics should be included. When clinically appropriate, the patient can be switched to oral ciprofloxacin or doxycycline, without additional antibiotics. The duration of treatment—IV plus oral—is 60 days. Specific regimens for adults, children, and pregnant women are presented in [Table 109-2](#) (for limited casualty settings) and [Table 109-3](#) (for mass casualty settings).

1280

1281

TABLE 109-2 Therapy of Inhalational Anthrax in the Limited Casualty Setting

Patient Group	Initial Intravenous Therapy	Follow-up Oral Therapy	Duration
Adults	Ciprofloxacin, 400 mg every 12 hr <i>or</i> Doxycycline, 100 mg every 12 hr <i>and</i> All patients should get 1 or 2 additional antibiotics. Options include rifampin, vancomycin, penicillin, ampicillin, imipenem, chloramphenicol, clindamycin, and clarithromycin. Do not use penicillin or ampicillin alone.	When clinically appropriate, switch to oral antibiotics: Ciprofloxacin, 500 mg twice daily <i>or</i> Doxycycline, 100 mg twice daily	60 days total (IV and PO combined)
Children	Ciprofloxacin, 10–15 mg/kg every 12 hr, but no more than 1 gm/day <i>or</i> Doxycycline (for young children): >8 yr and >45 kg: 100 mg every 12 hr >8 yr and ≤45 kg: 2.2 mg/kg every 12 hr ≤8 yr: 2.2 mg/kg every 12 hr <i>As with adults, all patients should get 1 or 2 additional antibiotics.</i>	When clinically appropriate, switch to oral antibiotics: Ciprofloxacin, 10–15 mg/kg every 12 hr, but no more than 1 gm/day <i>or</i> Doxycycline (for young children): >8 yr and >45 kg: 100 mg every 12 hr >8 yr and ≤45 kg: 2.2 mg/kg every 12 hr ≤8 yr: 2.2 mg/kg every 12 hr	60 days total (IV and PO combined) 60 days total (IV and PO combined)
Pregnant	Same as nonpregnant adults	Same as nonpregnant adults	
Data from Inglesby TV, et al: Anthrax as a biological weapon, 2002: Updated recommendations for management. JAMA 287:2236–2252, 2002.			

TABLE 109-3 Therapy of Inhalational Anthrax in the Mass Casualty Setting

Patient Group	Preferred Initial Oral Therapy	Alternative Oral Therapy (if Strain Is Proved Susceptible)	Duration
Adults	Ciprofloxacin, 500 mg every 12 hr	Doxycycline, 100 mg every 12 hr Amoxicillin, 500 mg every 8 hr	60 days
Children	Ciprofloxacin, 10–15 mg every 12 hr, but no more than 1 gm/day	≥20 kg: amoxicillin, 500 mg every 8 hr <20 kg: amoxicillin, 13.3 mg/kg every 8 hr	60 days
Pregnant	Ciprofloxacin, 500 mg every 12 hr	Amoxicillin, 500 mg every 8 hr	60 days
Data from Inglesby TV, et al: Anthrax as a biological weapon, 2002: Updated recommendations for management. JAMA 287:2236–2252, 2002.			

110.1.1.3.2 Cutaneous Anthrax.

Cutaneous anthrax is treated with oral antibiotics. The preferred drugs are *ciprofloxacin* and *doxycycline*. Dosages for adults, children, and pregnant women are the same as those given in [Table 109-2](#) for follow-up oral therapy of inhalational anthrax. Duration of treatment is 60 days. It should be noted that treatment is unlikely to prevent cutaneous lesions, but *will* prevent systemic complications.

110.1.1.4 Pre-exposure Vaccination

Currently, only one anthrax vaccine—*BioThrax* (formerly known as Anthrax Vaccine Adsorbed or AVA)—is licensed for use in the United States. BioThrax is an inactivated, cell-free preparation made from an avirulent strain of *B. anthracis*. The normal immunization schedule calls for three subcutaneous injections given 2 weeks apart, followed by three more injections given at 6, 12, and 18 months. Annual booster shots are recommended thereafter. The most common side effects are muscle and joint aches (20%); headache (20%); local redness, tenderness, or itching (10%); fatigue (10%); nausea (5%); and chills and fever (5%). Serious allergic reactions occur rarely (less than 1 in 100,000).

Who should receive anthrax vaccine? At this time, immunization is limited to people considered at risk. BioThrax is approved only for immunizing (1) people who handle animal products such as hides, hair, or bones that come from anthrax-endemic areas; and (2) people at high risk of exposure to anthrax spores, including veterinarians, laboratory workers, and others whose occupation may involve handling potentially infected animals or other contaminated materials. In addition to these approved uses, BioThrax is being used to vaccinate military personnel. Because the risk of infection in most people is low, routine vaccination of the general population is neither approved nor recommended.

110.1.1.5 Postexposure Prophylaxis: Antibiotics Plus Vaccination

To prevent infection following exposure to aerosolized anthrax spores, the Centers for Disease Control and Prevention (CDC) recommends treatment with an oral antibiotic plus anthrax vaccine. Antibiotic regimens are the same ones employed for treating inhalational anthrax in a mass casualty setting (see [Table 109-3](#)). Dosing should begin immediately and continue for at least 60 days.

Vaccination following anthrax exposure consists of three doses of BioThrax, given at 0, 2, and 4 weeks. As noted, BioThrax is not currently licensed for postexposure use, or for use in a three-dose regimen. Accordingly, such emergency use would be conducted under an Investigational New Drug application.

New recombinant vaccines are in development. However, when they will be available is uncertain. The leading candidate, produced by VaxGen, will *not* be available: After VaxGen failed to meet a series of deadlines, the U.S. government cancelled its contract with the company for 75 million doses.

110.1.2 *Francisella tularensis* (Tularemia)

Tularemia, also known as “rabbit fever” and “deer fly fever,” is a potentially fatal disease caused by *Francisella tularensis*, one of the most infectious bacteria known. Inoculation with as few as 10 microbes can cause disease. Infection can be acquired through the skin, mucous membranes, GI tract, or lungs. Terrorists trying to spread tularemia would most likely deliver the bacteria as an aerosol. Tularemia cannot be transmitted person to person.

110.1.2.1 Clinical Manifestations.

Symptoms of tularemia develop in 3 to 5 days. Initially, patients present with an acute flu-like illness, characterized by fever (38°C to 40°C), headache, chills, rigors, body aches, sneezing,

and sore throat. Pneumonia and pleuritis can develop in the ensuing days to weeks. In the absence of treatment, tularemia can progress to respiratory failure, shock, and death.

110.1.2.2 Treatment.

Tularemia responds well to antibiotics. The treatment of choice is *IM streptomycin* (15 mg/kg twice a day for 10 days). The preferred alternative is *gentamicin* (5 mg/kg IM or IV once a day for 10 days). If there is a mass outbreak, oral therapy with doxycycline or ciprofloxacin is recommended. Individuals who have not yet developed symptoms may benefit from prophylactic use of oral doxycycline or ciprofloxacin.

110.1.3 *Yersinia pestis* (Pneumonic Plague)

Plague is a potentially fatal disease caused by *Yersinia pestis*, a gram-negative bacillus. The disease has two principal forms: *bubonic* (characterized by tender, enlarged, and inflamed lymph nodes) and *pneumonic* (characterized by inflammation of the lungs). Bubonic plague is acquired through the bite of a plague-infected flea, and *cannot* be transmitted person to person. Rarely, an individual with bubonic plague develops secondary pneumonic plague, which *can* be transmitted person to person (by coughing). *Primary* pneumonic plague is acquired by inhaling aerosolized *Y. pestis*. The source of the aerosol could be a person with pneumonic plague, or it could be a biologic weapon. To a would-be bioterrorist, *Y. pestis* is attractive for several reasons: The microbe is readily available worldwide, culturing large quantities is relatively easy, the bacterium can be aerosolized for wide dissemination, pneumonic plague can be spread person to person, and the fatality rate is high.

1281

1282

110.1.3.1 Clinical Manifestations.

Symptoms of primary pneumonic plague usually develop 2 to 4 days after inhaling aerosolized *Y. pestis*. Patients typically present with high fever, cough, dyspnea, and hemoptysis (expectoration of blood or blood-stained sputum). Gastrointestinal symptoms—nausea, vomiting, diarrhea, and abdominal pain—may also develop. In the absence of treatment, the infection rapidly progresses to respiratory failure and death.

110.1.3.2 Treatment.

Antibiotics can be lifesaving—provided they are given early (before or shortly after symptom onset). Treatments of choice are (1) *streptomycin*, 15 mg/kg IM twice daily for 10 days; and (2) *gentamicin*, 5 mg/kg IM or IV once daily for 10 days. Preferred alternatives, all given IV, are doxycycline, ciprofloxacin, and chloramphenicol. In a mass-casualty setting, which may

preclude IV or IM administration, oral therapy with doxycycline (100 mg twice daily) or ciprofloxacin (500 mg twice daily) is recommended. There is no vaccine to protect against pneumonic plague.

110.1.4 Variola Virus (Smallpox)

Smallpox is a serious, contagious, life-threatening disease caused by the *variola virus*, a member of the genus *Orthopoxvirus*. The only natural reservoir for the virus is humans. We have no specific treatment for smallpox, but we *can* prevent the disease by vaccination, given either before exposure or within a few days after. Because smallpox is highly contagious and because the fatality rate is high (30%), the disease represents a grave threat as a weapon of terrorism.

Thanks to a global vaccination program, endemic smallpox has been eradicated. The last case in the United States occurred in 1949, and the last case on the planet occurred in Somalia in 1977. Because the threat of smallpox had been eliminated, routine vaccination was discontinued—in 1972 for Americans, and by 1982 for the rest of the world.

Ironically, the successful elimination of smallpox has set the stage for its potential return as a weapon of terrorism. That is, if we hadn't eradicated natural smallpox, then vaccination would still be ongoing. As a result, the population would have immunity, making smallpox useless as a weapon.

110.1.4.1 Pathogenesis and Clinical Manifestations

Variola virus enters the body through mucous membranes of the respiratory tract, usually as a result of virus inhalation. Initial exposure is followed by an asymptomatic incubation period (usually 12 to 14 days), followed by the prodromal phase (2- to 4-day duration), manifesting as high fever, malaise, prostration, headache, and backache. Viral invasion of the oral mucosa and dermis then leads to characteristic eruptions. Small red spots develop in the mouth and on the tongue, and then evolve into sores that break open, releasing large amounts of virus into the mouth and throat. Around this time, a bumpy skin rash develops, starting on the face and then quickly spreading over the entire body. Within 1 to 2 days, the bumps become vesicular (fluid filled), and then pustular (pus filled). About 8 or 9 days after rash onset, the pustules begin to form a crust and then a scab. By 3 weeks after the rash began, the scabs fall off, leaving a characteristic pitted scar.

About 30% of people with smallpox die, usually during the second week of illness. The most likely cause is toxemia associated with circulating immune complexes and soluble variola antigens.

110.1.4.2 Transmission

Natural smallpox is transmitted person to person. It is not transmitted by insects or animals. Transmission occurs primarily by touching an infected person or by inhaling aerosolized droplets expelled from the oropharynx. Smallpox can also be acquired by contact with contaminated clothing or bedding. The disease is somewhat contagious during the prodromal phase, but is most contagious from the onset of rash through scab formation. After all scabs fall off, infectivity is gone.

If used as a weapon, variola virus would most likely be disseminated as an aerosol. Because the virus is fragile, at least 90% of the amount released into the environment would become inactive within 24 hours.

110.1.4.3 Treatment

There is no proven treatment for smallpox. However, research with newer antiviral drugs is ongoing. Several agents show promise, including *cidofovir*, *adefovir*, and *ribavirin*. Topical *idoxuridine* may benefit patients with corneal lesions. Antibiotics should be used to treat secondary bacterial infections.

110.1.4.4 Smallpox Vaccine

Vaccination is the only way to prevent smallpox. In addition to conferring protection when given *prior to* viral exposure, the vaccine confers protection when given within a few days *after* exposure. For 30 years—between 1972 and 2002—vaccination in the United States had been limited to the few scientists and medical professionals who do research on smallpox and related viruses. However, owing to concerns about bioterrorism, the U.S. government has reinstituted vaccination. Mandatory vaccination of military personnel began in 2002. Voluntary vaccination of selected civilian groups began in 2003. At this time, smallpox vaccine is not available to the general public—nor is it recommended. However, in the event of a terrorist attack, prophylactic immunization will be offered.

110.1.4.4.1 Description.

The vaccine in current use is a suspension of live *vaccinia virus*, a virus that belongs to the same family as variola virus, but does not cause smallpox. From 1931 to 2007, only one vaccine—*Dryvax*—was licensed for use in the United States. In 2007, the FDA approved a new vaccine—*ACAM2000*—and withdrew the license for *Dryvax*. Both vaccines are very

similar. In fact, ACAM2000 is produced from a clone of the vaccinia strain used to make Dryvax. The principal difference between the vaccines is that ACAM2000 is manufactured using modern cell-culture technology, whereas Dryvax is processed from calf lymph. Following the introduction of ACAM2000, all existing stocks of Dryvax were destroyed.

An even newer vaccine, named *Imvamune*, is in clinical trials. Imvamune is made with *modified vaccinia virus Ankara* (MVA), a virus that is immunogenic but unable to replicate in humans. As a result, even though the vaccine contains live viruses, it is not dangerous for people who are immunocompromised. (In immunocompromised subjects, the viruses in ACAM2000 can proliferate and cause serious injury, and hence ACAM2000 is generally contraindicated for such people.) In animal models, MVA was considerably safer than Dryvax, and nearly as effective. In 2007, the Department of Health and Human Services contracted with the manufacturer of Imvamune to buy 20 million doses of the vaccine, even though the product is not yet licensed in this country.

1282

1283

110.1.4.4.2 Efficacy.

Vaccination before exposure to variola virus prevents smallpox in about 95% of vaccinees. Vaccination within 3 days after exposure also confers significant protection, preventing symptoms entirely in some people, and greatly reducing symptoms in others. Benefits of vaccination 4 to 7 days after exposure are uncertain.

110.1.4.4.3 Duration of Protection.

Successful primary vaccination produces a high level of immunity for 5 to 10 years, with slowly decreasing immunity thereafter. However, it is not clear just when effective protection is lost. Data from a 2008 study indicate that titers of neutralizing antibodies in people vaccinated 13 to 88 years ago are comparable to those in people vaccinated recently, suggesting long-term persistence of specific immunity.

110.1.4.4.4 Administration.

Smallpox vaccine is administered by a unique method known as *scarification*, which introduces the vaccine through multiple skin punctures. Administration is not by subQ, IM, or IV injection. The vaccine is given with a bifurcated (two-pronged) needle that is dipped into the vaccine solution. When removed from the solution, the needle retains a droplet of vaccine between the prongs. The administrator then pricks the skin several times (2 or 3 times for primary vaccination; 15 times for revaccination). The resulting punctures should be superficial, but still deep enough to allow a trace of blood to appear after 15 to 20 seconds.

Vaccinations are made in the upper arm. To prevent spread of the vaccine, which contains live viruses, the site should be covered with sterile gauze or a semipermeable membrane.

110.1.4.4.5 Interpreting the Response.

Successful vaccination is indicated when the following events take place. Within 3 to 4 days, a red, itchy bump appears. During the first week, the bump becomes a blister, fills with pus, and then starts to drain. During the second week, the blister begins to dry and develops a scab. In the third week, the scab falls off, leaving a small scar. Reactions to primary vaccination are stronger than reactions to revaccination.

110.1.4.4.6 Adverse Effects.

The smallpox vaccine may carry considerable risk. Past experience suggests that, if 1 million people were vaccinated, 1000 would experience a serious adverse effect, 14 to 52 would develop a life-threatening condition, and 1 or 2 would die. However, recent data suggest the risk is lower. Regardless of what the real level of risk from vaccination may be, there is no question that the risk of smallpox infection is far greater. Accordingly, anyone exposed to variola virus should be offered the vaccine.

110.1.4.4.6.1 Mild Effects.

In addition to the local reactions that signal a successful immune response, vaccination can cause local inflammation, along with swelling and tenderness in regional lymph nodes. Transient symptoms typical of viral illness (fever, headache, muscle aches, fatigue) are also common.

If the vaccination site is not securely covered, vaccinia virus can be transferred to other areas—usually the face, eyelids, nose, mouth, or genitalia—as well as to other people. Transfer to the eyes can cause sight-threatening keratitis. However, most lesions heal spontaneously.

110.1.4.4.6.2 Moderate to Severe Effects.

Serious reactions to smallpox vaccination include eczema vaccinatum, generalized vaccinia, progressive vaccinia, postvaccinial encephalitis, and fetal vaccinia. (The terms *vaccinatum* and *vaccinia* in the names of these disorders simply refer to the cause: vaccinia virus.)

Eczema vaccinatum occurs when infection with vaccinia virus is superimposed on a pre-existing skin condition, usually eczema or atopic dermatitis. As a rule, the disorder is mild and self-limiting. However, in some people it can be life threatening.

Generalized vaccinia is a widespread vesicular rash that resembles smallpox. The cause is transient viremia with localization in the skin. Although the condition is generally self-limiting, it can be severe in the immunocompromised patient.

Progressive vaccinia, also called *vaccinia necrosum*, is a rare but often fatal condition that develops almost exclusively in patients who are immunodeficient. The condition is characterized by progressive necrosis at the inoculation site, often associated with metastatic vaccinia lesions at distant sites (skin, bones, and viscera).

Postvaccinial encephalitis (inflammation of the brain) is rare but dangerous. This complication occurs roughly 2 to 12 times per million vaccinations. The fatality rate is 15% to 25%, and 25% of survivors suffer brain damage.

Fetal vaccinia is a very rare but serious infection of the fetus, manifested by skin lesions and internal organ involvement. The condition can lead to premature birth, or fetal or neonatal death. Fetal vaccinia can result from exposure to vaccinia virus at any stage of pregnancy. Accordingly, women who are pregnant should not get the vaccine. Women who were recently vaccinated should wait at least 4 weeks before attempting to become pregnant.

110.1.4.4.6.3 Possible Cardiac Effects.

Some vaccinees have developed cardiac problems—specifically, myocarditis (inflammation of the heart muscle), pericarditis (inflammation of the pericardium), myocardial infarction (heart attack), and angina pectoris (ischemic cardiac pain). However, a definite link between vaccination and these disorders has not been established. Until more is known, routine vaccination should be withheld from people with established heart disease (heart failure, angina, myocardial infarction, cardiomyopathy), and from those with three or more cardiovascular risk factors (see [Table 109-4](#)).

110.1.4.4.7 Management of Adverse Effects.

Two agents—*vaccinia immune globulin* (VIG) and *cidofovir* [Vistide]—can be given to treat severe reactions to smallpox vaccine. However, neither preparation is approved for this use.

VIG is a solution that contains immunoglobulins from people vaccinated with vaccinia virus, and hence should contain antibodies directed against the virus. However, therapeutic effects have not been established in controlled trials. There is some evidence that VIG can benefit those with eczema vaccinatum or generalized vaccinia, and possibly those with progressive vaccinia. In contrast, the preparation is of no help to those with postvaccinial encephalitis, and may actually *increase* corneal damage in those with vaccinial keratitis. VIG is administered IM into the buttocks or anterolateral thigh. The dosage is 0.6 mL/kg, repeated every 2 to 3 days as needed. VIG is available only from the CDC.

1283
1284

TABLE 109-4 Medical Conditions and Other Factors That
Contraindicate Routine Smallpox Vaccination*

<ul style="list-style-type: none">• History of eczema or atopic dermatitis• Active skin conditions, including burns, herpes, severe acne, psoriasis, chickenpox, or shingles (delay vaccination until lesions heal)• Immunodeficiency (caused by HIV infection, primary immunodeficiency disorder, or use of immunosuppressive drugs, including glucocorticoids, many anticancer drugs, and drugs used to prevent transplant rejection)†• Pregnancy (or plans to become pregnant within 1 month of vaccination)• Breast-feeding• Allergy to the smallpox vaccine or any of its components (polymyxin B, streptomycin, chlortetracycline, neomycin)• Age less than 18 years (and especially less than 1 year) or greater than 65 years• Moderate or severe short-term illness (delay vaccination until illness resolves)• Inflammatory eye disease with ongoing use of steroid eye drops• Heart conditions, including heart failure, angina, myocardial infarction, and cardiomyopathy• Three or more cardiovascular risk factors: hypertension, high cholesterol, diabetes, cigarette use, first-degree relative with early heart disease (ie, before the age of 50)
* Routine vaccination should be avoided in people with these conditions. However, vaccination is indicated following exposure to the smallpox virus.
† Unlike ACAM2000, the MVA-based vaccine—Imvamune—should be safe for immunocompromised patients.

Cidofovir is an antiviral drug with one approved indication: cytomegalovirus retinitis in patients with AIDS. However, in animal studies, the drug also showed good activity against vaccinia virus. Accordingly, some authorities recommend it for patients with severe vaccination complications, including progressive vaccinia, generalized vaccinia, and eczema vaccinatum. The pharmacology of cidofovir is discussed in [Chapter 92](#) (Antiviral Agents I: Drugs for Non-HIV Viral Infections).

110.1.4.4.8 Who Should NOT Be Vaccinated?

Certain conditions (eg, eczema, atopic dermatitis, immunodeficiency, pregnancy) increase the risk of a serious reaction to smallpox vaccine. Accordingly, people who have these conditions, or who live with someone who does, should not be vaccinated—unless, of course, they have been exposed to the smallpox virus, in which case the risk of infection would far outweigh the risk of the vaccine. [Table 109-4](#) gives a full list of medical conditions and other factors that contraindicate routine vaccination.

11... BIOTOXINS

110.2.1 Botulinum Toxin

Botulinum toxin, produced by *Clostridium botulinum*, is the most potent poison known. Just 1 gram, if evenly dispersed and inhaled, could kill more than 1 million people. For use as a weapon of terrorism, the toxin could be delivered as an aerosol or simply put into food. And yes, this is the same agent used to iron out wrinkles (see [Chapter 104](#), [Box 104-1](#), *Face Time with Botox*).

110.2.1.1 Mechanism of Action.

How does botulinum toxin work? It blocks release of acetylcholine from cholinergic neurons. The toxin is taken up by cholinergic nerve terminals, where it then inactivates SNAP-25, a protein critical to the function of acetylcholine-containing vesicles. In the absence of SNAP-25, the vesicles are unable to fuse with the nerve-terminal membrane, and hence cannot release their acetylcholine into the synaptic space. Restoration of neuronal function requires sprouting of new terminals, a process that can take several months. Botulinum toxin blocks transmission at neuromuscular junctions and at cholinergic synapses of the autonomic nervous system.

110.2.1.2 Clinical Manifestations.

Poisoning is characterized by symmetric, descending flaccid paralysis, beginning 12 to 72 hours after exposure and persisting for weeks to months. Classic symptoms are double vision, blurred vision, drooping eyelids, slurred speech, dry mouth, difficulty swallowing, and muscle weakness that descends through the body, starting with the shoulders, and then progressing to the upper arms, lower arms, thighs, calves, and feet. Death results from paralysis of the muscles of respiration.

110.2.1.3 Treatment.

Treatment consists of prolonged supportive care and immediate infusion of botulinum antitoxin (botulism immune globulin). Supportive care, which may be needed for several months, includes fluid and nutritional therapy plus mechanical assistance of ventilation. Botulinum antitoxin, produced in horses, should be given as soon as botulism is diagnosed. The antiserum, which contains neutralizing antibodies, can minimize further nerve damage, but cannot reverse damage that has already set in. In the United States, botulinum antitoxin is available only through state and local health departments, which get their supply from the CDC. The recommended dosage is 10 mL (the contents of 1 vial) diluted 1:10 in 0.9% saline and administered by slow IV infusion. In 2003, the FDA approved a new antitoxin formulation, available as *BabyBIG*, for treating children under 1 year old.

110.2.2 Ricin

Ricin is a toxin present in castor beans, which are produced by *Ricinus communis*, the castor-bean plant. The toxin is manufactured by extraction from the “mash” left behind when castor beans are processed to make castor oil. When purified, ricin can be formulated as a powder, pellet, or mist, or dissolved in water or a weak acid.

110.2.2.1 Mechanism of Action.

Ricin promotes injury by disrupting protein production. How? Ricin is an enzyme that catalyzes the inactivation of ribosomes, which are required for protein synthesis. Inhibition of protein synthesis leads to cell death and related tissue injury.

110.2.2.2 Clinical Manifestations.

Symptoms of poisoning depend on the route of administration:

- *Inhalation*—Within a few hours of inhaling ricin mist or powder, the victim can experience coughing, tightness in the chest, difficulty breathing, nausea, and muscle ache. A few hours later, the airway may become severely inflamed and edematous, making breathing extremely difficult. Cyanosis and death can follow.

1284

- *Ingestion*—Swallowing a significant dose can cause gastric and intestinal hemorrhage, associated with vomiting and bloody diarrhea. In time, the liver, spleen, and kidneys may fail. Death can occur within 10 to 12 days of ingestion.

1285

- *Injection*—Injection of ricin can lead to severe symptoms and death. However, this route is obviously impractical for terrorism.

110.2.2.3 Treatment.

Management of poisoning is purely supportive. We have no antidote for ricin. A vaccine to protect against ricin is in development.

11... CHEMICAL WEAPONS

110.3.1 Nerve Agents

Nerve agents are “irreversible” organophosphate cholinesterase inhibitors. By inhibiting cholinesterase, these drugs increase the concentration of acetylcholine at neuromuscular junctions, cholinergic synapses in the central nervous system (CNS), and all autonomic synapses that employ acetylcholine as a transmitter. Toxic doses produce a state of cholinergic crisis, characterized by excessive muscarinic stimulation and depolarizing neuromuscular blockade. Treatment consists of (1) mechanical ventilation using oxygen, (2) giving *atropine* to reduce muscarinic stimulation, (3) giving *pralidoxime* to reverse inhibition of cholinesterase (primarily at neuromuscular junctions), and (4) giving *diazepam* to suppress convulsions. Specific nerve agents that might be used for a terrorist attack include *soman*, *tabun*, *sarin*, and *cyclosarin*. All are volatile at room temperature. However, nerve agent vapors are denser than air, and hence tend to accumulate in low-lying areas. The toxic effects of nerve agents and the use of pralidoxime for treatment are discussed at length in [Chapter 15](#) (Cholinesterase Inhibitors and Their Use in Myasthenia Gravis) under the heading *Toxicology* in the section on “Irreversible” *Cholinesterase Inhibitors*.

^{110.3.2}Sulfur Mustard (Mustard Gas)

^{110.3.2.1} Properties.

Sulfur mustard (bis[2-chloroethyl]sulfide), also known as mustard gas, is an alkylating agent and vesicant (chemical blistering agent). However, the precise relationship between alkylation of DNA (and other cellular components) and production of blisters is unclear. Physically, sulfur mustard is a lipophilic, oily liquid that can be vaporized at high temperatures. For use as a weapon of terrorism, sulfur mustard could be vaporized into the air or released into the water supply. Injuries from sulfur mustard can be severe, but the fatality rate is low. When used as a weapon in World War I, sulfur mustard killed less than 5% of its victims.

^{110.3.2.2} Clinical Manifestations.

Symptoms of toxicity depend on the dose, the tissue involved, and the duration of exposure. As a rule, symptoms are delayed, usually taking 2 to 24 hours to develop. Effects on specific tissues are as follows:

- *Skin*—Dermal contact causes pain, redness, swelling, and blisters (small to very large). Symptoms appear within 4 to 48 hours, depending on the dose. Areas where the skin is warm, moist, and thin are most vulnerable.
- *Eyes*—The eyes are exquisitely sensitive to sulfur mustard. Moderate exposure can produce irritation, pain, swelling, and tearing in 3 to 12 hours. Severe exposure can cause corneal burns, necrosis, severe pain, and blindness, which may last up to 10 days.
- *Respiratory tract*—Symptoms appear 2 to 24 hours after inhaling sulfur mustard. Mild exposure can cause runny nose, sneezing, hoarseness, sinus pain, and a dry, barking cough. Severe exposure can cause hemorrhage and necrosis of lung tissue, evidenced by coughing up blood.
- *GI tract*—Ingestion can cause nausea, vomiting, diarrhea, and abdominal pain. Symptoms typically develop within a few hours and resolve within 24 hours.
- *Bone marrow*—Very high doses cause bone marrow suppression, resulting in neutropenia and thrombocytopenia.

110.3.2.3 Treatment.

Management centers on rapid decontamination, supportive care, and drug therapy. People exposed to sulfur mustard should undress immediately and wash 3 times with soap and water. Those with significant airway damage may need intubation. Severe skin burns are treated by irrigation, débridement, and application of topical antibiotics; burn-related pain can be controlled with an opioid analgesic. Exposed eyes should be irrigated; other treatments include use of cycloplegics/mydriatics, application of topical antibiotics, and application of petroleum jelly to prevent burned lids from sticking. Granulocyte colony-stimulating factor can be used to stimulate neutrophil production by bone marrow.

11... RADIOLOGIC WEAPONS

110.4.1 Weapon Types

110.4.1.1 Nuclear Bombs

Nuclear bombs present an *immediate* threat from the blast itself and a *delayed* threat from radioactive fallout. Immediate harm is produced in four ways:

- The explosion and its shock wave damage buildings, people, and everything else they reach.
- Intense heat causes injury directly and by igniting fires.
- Intense light damages eyesight.
- Ionizing radiation causes acute radiation syndromes and radiation sickness, characterized by nausea, vomiting, diarrhea, fatigue, dehydration, inflammation, skin burns, hair loss, and ulceration of the mouth, esophagus, and GI tract. Symptoms develop over days to weeks. For those who survive, radiation exposure increases the risk of cancer.

Radioactive fallout, mainly *iodine-131*, poses a delayed risk. Specifically, it poses a risk of thyroid cancer. A nuclear explosion creates a radioactive cloud that can spread fallout over a large area. Contamination of humans can result from inhaling fallout, touching contaminated objects, or ingesting contaminated water and food. Once in the body, iodine-131 becomes concentrated in the thyroid gland, where it can cause thyroid cancer. The risk of cancer can be reduced by ingesting potassium iodide, which blocks uptake of radioactive iodine by the thyroid (see below).

110.4.1.2 Attacks on Nuclear Power Plants

Terrorists could attack a nuclear power plant, either with a bomb or by using sabotage to cause meltdown of the radioactive core. In either case, a large amount of radiation could be released. 1285
1286

Please note, however, that an attack would *not* cause a nuclear explosion. People in the immediate area could suffer severe radiation exposure, resulting in acute radiation syndrome or radiation sickness. As in a nuclear blast, release of iodine-131 could pose a risk of thyroid cancer.

110.4.1.3 Dirty Bombs (Radiologic Dispersion Devices)

A dirty bomb is a device that uses a conventional explosive (eg, dynamite) to disperse radioactive material that has been formulated as a powder or tiny pellets. Resultant radioactive contamination could be external or internal (owing to inhalation, ingestion, or absorption through a wound). However, it is important to appreciate that the primary danger from a dirty bomb is the blast itself, not the radiation. Why? Because the sources of radiation likely to be used are not very dangerous, and because dispersal of radiation would be limited to a relatively small area. The risk of cancer is very low. Persons exposed to a dirty bomb blast should remove their clothes as soon as possible, and then decontaminate their skin by showering. A dirty bomb will not release iodine-131, and hence taking potassium iodide would be of no benefit.

110.4.2 Drugs for Radiation Emergencies

110.4.2.1 Potassium Iodide

Potassium iodide (KI) is used to block uptake of radioactive iodine by the thyroid gland, and thereby protect the thyroid from radiation damage. To be effective, KI must be taken soon after exposure. If taken 48 hours after exposure, the drug is useless. Each dose protects for about 24 hours. Daily dosages recommended by the CDC are as follows:

- *Age up to 1 month:* 16 mg
- *Age 1 month to 3 years:* 32 mg
- *Age 3 years to 18 years:* 65 mg
- *Age 18 years and older:* 130 mg
- *Females who are breast-feeding, regardless of age:* 130 mg

How often should dosing be done? In most cases, the environment will be clear of radioactive iodine quickly, and hence a single dose is usually sufficient. If contamination persists, then dosing can be repeated once every 24 hours until radioactive iodine levels decline. However, repeat dosing with KI must be *avoided* by newborn infants and by women who are pregnant or breast-feeding; these people should be evacuated until the threat is gone.

Potassium iodide is available in two oral formulations: tablets (65 and 130 mg) and liquid (65 mg/mL). No prescription is needed.

110.4.2.2 Penetrate Zinc Trisodium and Penetrate Calcium Trisodium

Penetrate zinc trisodium (Zn-DTPA) and penetrate calcium trisodium (Ca-DTPA) are used to treat people who have internal contamination with plutonium, americium, or curium. Benefits derive from accelerating removal of these radioactive isotopes from the body. Both drugs form stable complexes, known as chelates, with plutonium, americium, and curium (and other metals too), and the chelates are then excreted in the urine. The drugs do not bind strongly with radioactive iodine, uranium, or neptunium, and hence cannot be used to remove these isotopes. To monitor treatment, radioactivity in the blood, urine, and feces should be measured at baseline and weekly thereafter.

Penetrate zinc and penetrate calcium are usually administered IV, but may also be inhaled (if exposure is limited to the lungs). Absorption from the GI tract is very low, and hence oral therapy cannot be used. Once in the blood, both drugs distribute rapidly throughout extracellular fluid, but they do not penetrate cells. Metabolism is minimal. Both drugs undergo glomerular filtration followed by excretion in the urine. In patients with normal renal function, clearance occurs within a few hours after dosing. However, in patients with renal impairment, clearance is much slower. Nonetheless, dosage is not reduced for these people. Rather, high-efficiency, high-flux dialysis is employed to promote drug removal.

Therapy is most effective when initiated within 24 hours of radiation exposure. Why? Because, as time passes, the radiocontaminants become sequestered in liver and bone, making them harder to remove. Nonetheless, since delayed treatment is better than no treatment at all, dosing should begin as soon as the drugs are available. For the first 24 hours after exposure, Ca-DTPA is more effective than Zn-DTPA, and hence Ca-DTPA should be used initially. After 24 hours, both drugs are equally effective.

Dosing is done once a day—usually by slow IV push or IV infusion—and may continue for months. The exact duration depends on the degree of radioactive contamination and drug

efficacy. For adults and adolescents, the recommended daily IV dose is 1 gm. For children under 12 years old, the daily IV dose is 14 mg/kg (but no more than 1 gm). To reduce the concentration of radioactive chelate in the urine, and thereby reduce the risk of injury to the bladder, patients should drink lots of fluid and void often.

Because Zn-DTPA and Ca-DTPA chelate metals, prolonged treatment can lead to trace-metal depletion. Both drugs can reduce body stores of manganese and magnesium, and Ca-DTPA can also reduce stores of zinc. Serum levels of trace metals should be monitored, and supplements provided if the levels are low.

110.4.2.3 Prussian Blue

Prussian blue [Radiogardase], also known as *ferric hexacyanoferrate*, is used to hasten excretion of radioactive cesium and radioactive and nonradioactive thallium. Prussian blue is an insoluble, nonabsorbable compound, taken orally, that binds tightly with cesium and thallium in the intestine. In the absence of Prussian blue, both isotopes undergo extensive enterohepatic recirculation. That is, they undergo absorption into the blood, followed by excretion in the bile, followed by reabsorption, and so forth—a cycle that extends their stay in the body. However, when bound with Prussian blue, cesium and thallium cannot be reabsorbed, and hence must stay in the intestine for excretion. Food may accelerate the elimination. Why? Because food increases production of bile, and hence may increase the rate at which cesium and thallium are presented to Prussian blue in the intestine.

Prussian blue can cause constipation, which is a concern for two reasons. First, constipation can delay excretion of radioactive contaminants. Second, it can increase the dose of radiation absorbed by the GI mucosa. If constipation occurs, it can be treated with a fiber-based laxative, a high-fiber diet, or both. Prussian blue should be used with caution in patients with decreased GI motility.

1286

Prussian blue can bind with potassium and other electrolytes. Some patients have developed hypokalemia. To reduce risk, serum electrolytes should be monitored closely. Exercise caution in patients with cardiac dysrhythmias (which are sensitive to hypokalemia) or pre-existing electrolyte imbalance.

1287

Prussian blue [Radiogardase], in the form of a blue powder, is supplied in 500-mg gelatin capsules. Dosing is done 3 times a day. For adults and adolescents, each dose is 3 gm. For children 2 to 12 years old, each dose is 1 gm. If needed, the capsules may be opened and the powder mixed with bland foods or liquids. However, be aware that opening the capsules may

result in blue discoloration of the mouth and teeth. Whether the capsules are swallowed intact or opened, Prussian blue will turn stools blue; patients should be forewarned.

To monitor treatment, radioactivity in urine and stool samples should be measured at baseline and periodically thereafter. Whole-body radioactivity should be measured as appropriate.

110.4.2.3.1

KEY POINTS

- Anthrax is a potentially fatal disease caused by *Bacillus anthracis*, a bacterium that produces spores that can remain viable in the environment for decades.
- Anthrax infection is acquired when spores enter the body, typically through the skin or through mucous membranes of the respiratory tract.
- *Inhalational* anthrax is characterized by severe respiratory distress, septicemia, hemorrhagic meningitis, and shock. About 45% of victims die, even when treated.
- Lesions of *cutaneous* anthrax are characterized by a black eschar (scab-like structure) that eventually dries, loosens, and sloughs off. Most cases resolve without complications or scarring.
- For initial therapy of inhalational anthrax, treatments of choice are IV ciprofloxacin and IV doxycycline, combined with one or two additional IV antibiotics.
- Drugs of choice for cutaneous anthrax are oral ciprofloxacin and oral doxycycline.
- Anthrax vaccine is available for military personnel and selected others, but not yet for the general population.
- Tularemia is a potentially fatal disease caused by *Francisella tularensis*, one of the most infectious bacteria known.
- Tularemia can be acquired through bacterial invasion of the skin, mucous membranes, GI tract, or lungs.
- Tularemia is characterized by pneumonia and pleuritis that can progress to respiratory failure, shock, and death.
- Tularemia responds well to antibiotics. The treatment of choice is IM streptomycin.
- Pneumonic plague is a potentially fatal disease caused by *Yersinia pestis*.

- Pneumonic plague is acquired by inhaling aerosolized *Y. pestis*, and can be transmitted person to person.
- Pneumonic plague is characterized by high fever, cough, dyspnea, and hemoptysis (expectoration of blood or blood-stained sputum). In the absence of treatment, the infection rapidly progresses to respiratory failure and death.
- Treatments of choice for pneumonic plague are streptomycin (IM) and gentamicin (IM or IV).
- Smallpox is a contagious, potentially fatal disease caused by variola virus, whose only reservoir is humans.
- Worldwide vaccination has eliminated naturally occurring smallpox. The last case occurred in Somalia in 1977.
- Variola virus enters the body through mucous membranes of the respiratory tract.
- Smallpox is characterized by (1) eruptions on the mouth and tongue that release virus into the oropharynx and (2) pustules on the skin that release the virus on the body surface.
- Natural smallpox is transmitted person to person, primarily by touching an infected individual or by inhaling aerosolized droplets expelled from the oropharynx.
- There is no proven treatment for smallpox.
- The smallpox vaccine in current use, named ACAM2000, consists of live vaccinia virus. The vaccine confers protection when given before exposure to variola virus and when given within a few days after exposure.
- Successful primary vaccination with smallpox vaccine produces high-level immunity for at least 5 to 10 years. Significant immunity may persist for decades.
- Smallpox vaccination is not without risk: Past experience suggests that, if 1 million people were vaccinated, 1000 would experience a serious adverse effect, 14 to 52 would develop a life-threatening condition, and 1 or 2 would die.
- Although smallpox vaccination carries risk, the risk of smallpox itself is far greater. Accordingly, anyone exposed to variola virus should be offered the vaccine.

- Routine smallpox vaccination is contraindicated by a number of conditions, including eczema, atopic dermatitis, immunodeficiency, pregnancy, and heart disease.
- Botulinum toxin, produced by *Clostridium botulinum*, is the most potent poison known.
- Botulinum toxin acts on cholinergic nerve terminals to cause prolonged blockade of acetylcholine release.
- Poisoning with botulinum toxin is characterized by symmetric, descending flaccid paralysis, coupled with disturbed vision, drooping eyelids, slurred speech, dry mouth, and difficulty swallowing. Death results from paralysis of the muscles of respiration.
- Treatment of botulinum toxin poisoning consists of immediate infusion of botulinum antitoxin plus prolonged supportive care.
- Botulinum antitoxin can minimize further nerve damage, but cannot reverse damage that has already occurred.
- Ricin is a toxin present in castor beans (which are used to make castor oil).
- Ricin causes injury by inhibiting protein synthesis.
- When ricin is *inhaled*, it causes inflammation and edema of the airway, thereby making breathing extremely difficult. Cyanosis and death can follow.
- When ricin is *ingested*, it causes gastric and intestinal hemorrhage, associated with vomiting and bloody diarrhea. In time, the liver, spleen, and kidneys may fail.
- Management of ricin poisoning is purely supportive. There is no antidote.

1287

- Nerve agents cause “irreversible” inhibition of cholinesterase, and thereby increase the concentration of acetylcholine at neuromuscular junctions, cholinergic synapses in the CNS, and all autonomic synapses that employ acetylcholine as a transmitter.
- Nerve agents produce a state of cholinergic crisis, characterized by excessive muscarinic stimulation and depolarizing neuromuscular blockade.

1288

- Treatment of nerve agent poisoning consists of mechanical ventilation using oxygen, and giving atropine (to reduce muscarinic stimulation), pralidoxime (to reverse inhibition of cholinesterase), and diazepam (to suppress convulsions).
- Sulfur mustard (mustard gas) is an alkylating agent and vesicant that can injure any tissue that it reaches.
- Symptoms of sulfur mustard toxicity include large skin blisters, corneal burns, hemorrhage and necrosis of lung tissue, GI disturbances, and neutropenia and thrombocytopenia (secondary to bone marrow suppression).
- Management of sulfur mustard poisoning consists of rapid decontamination, supportive care, and drug therapy.
- A nuclear bomb presents an immediate threat from the blast itself (including acute radiation sickness) and a delayed threat from radioactive fallout.
- Iodine-131 in fallout poses a risk of thyroid cancer.
- The risk of thyroid cancer can be reduced by ingesting potassium iodide, which blocks uptake of iodine-131 by the thyroid.
- A terrorist attack on a nuclear power plant could cause the release of large amounts of radiation, including iodine-131, but would not cause a nuclear explosion.
- A dirty bomb is a device that uses a conventional explosive, such as dynamite, to disperse radioactive material.
- The primary danger from a dirty bomb is the blast itself, not the radiation.
- A dirty bomb will not release iodine-131, and hence taking potassium iodide is not indicated.
- Three compounds—penicillin, zinc trisodium, penicillin calcium trisodium, and Prussian blue—can hasten excretion of certain radioactive isotopes following internal contamination.

¹¹APPENDIX A Adult Immunization, United States, 2009

The immunization schedules shown in [Figures A-1](#) and [A-2](#) are based on joint recommendations by the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC), the American College of Obstetricians and Gynecologists (ACOG), and the American Academy of Family Physicians (AAFP). For detailed recommendations, consult the manufacturers' package inserts and the complete statements from the ACIP, which can be found online at www.cdc.gov/vaccines/pubs/ACIP-list.htm. Additional information about the vaccines listed is available at <http://www.cdc.gov/vaccines/> or from the CDC-INFO Contact Center at 800-CDC-INFO (800-232-4636) in English and Spanish, 24 hours a day, 7 days a week.

^{11...}IMMUNIZATION SCHEDULE NOTES**^{111.1.1}1. Tetanus, Diphtheria, and Acellular Pertussis (Td/Tdap) Vaccination**

Tdap should replace a single dose of Td for adults ages 19 through 64 years who have not received a dose of Tdap previously.

Adults with uncertain or incomplete history of primary vaccination series with tetanus and diphtheria toxoid-containing vaccines should begin or complete a primary vaccination series. A primary series for adults is three doses of tetanus and diphtheria toxoid-containing vaccines; administer the first two doses at least 4 weeks apart and the third dose 6 to 12 months after the second. However, Tdap can substitute for any one of the doses of Td in the three-dose primary series. The booster dose of tetanus and diphtheria toxoid-containing vaccine should be administered to adults who have completed a primary series and if the last vaccination was received 10 or more years previously. Tdap or Td vaccine may be used, as indicated.

If a woman is pregnant and received the last Td vaccination 10 or more years previously, administer Td during the second or third trimester. If the woman received the last Td vaccination less than 10 years previously, administer Tdap during the immediate postpartum period. A dose of Tdap is recommended for postpartum women, close contacts of infants less than 12 months of age, and all healthcare personnel with direct patient contact if they have not previously received Tdap. An interval as short as 2 years from the last Td vaccination is suggested; shorter intervals can be used. Td may be deferred during pregnancy and Tdap substituted in the immediate postpartum period, or Tdap may be administered instead of Td to a pregnant woman after an informed discussion with the woman.

Consult the ACIP statement for recommendations for administering Td as prophylaxis in wound management.

^{111.1.2}2. Human Papillomavirus (HPV) Vaccination

HPV vaccination is recommended for all females ages 11 through 26 years (and may begin at 9 years) who have not completed the vaccine series. History of genital warts, abnormal Papanicolaou test, or positive HPV DNA test is not evidence of prior infection with all vaccine HPV types; HPV vaccination is recommended for persons with such histories.

Ideally, vaccine should be administered before potential exposure to HPV through sexual activity; however, females who are sexually active should still be vaccinated consistent with age-based recommendations. Sexually active females who have not been infected with any of the four HPV vaccine types receive the full benefit of the vaccination. Vaccination is less beneficial for females who have already been infected with one or more of the HPV vaccine types.

A complete series consists of three doses. The second dose should be administered 2 months after the first dose; the third dose should be administered 6 months after the first dose.

HPV vaccination is not specifically recommended for females with the medical indications described in [Figure A-2](#). Because HPV vaccine is not a live virus vaccine, it may be administered to persons with the medical indications described in [Figure A-2](#). However, the immune response and vaccine efficacy might be less for persons with the medical indications described in [Figure A-2](#) than in persons who do not have the medical indications described or who are immunocompetent. Healthcare personnel are not at increased risk because of occupational exposure, and should be vaccinated consistent with age-based recommendations.

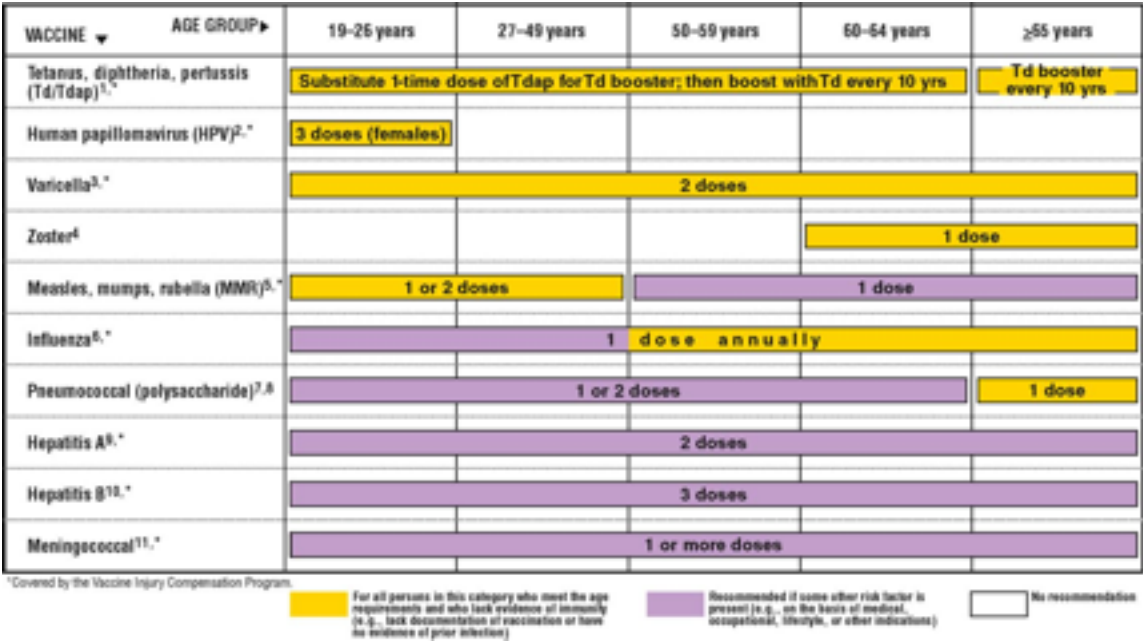

^{111.1.3}3. Varicella Vaccination

All adults without evidence of immunity to varicella should receive two doses of single-antigen varicella vaccine if not previously vaccinated or the second dose if they have received only one dose, unless they have a medical contraindication. Special consideration should be given to those who (1) have close contact with persons at high risk for severe disease (eg, healthcare personnel and family contacts of persons with immunocompromising conditions) or (2) are at high risk for exposure or transmission (eg, teachers; child-care employees; residents and staff members of institutional settings, including correctional institutions; college students; military personnel; adolescents and adults living in households with children; nonpregnant women of child-bearing age; and international travelers).

Evidence of immunity to varicella in adults includes any of the following: (1) documentation of two doses of varicella vaccine at least 4 weeks apart; (2) U.S.-born before 1980 (although

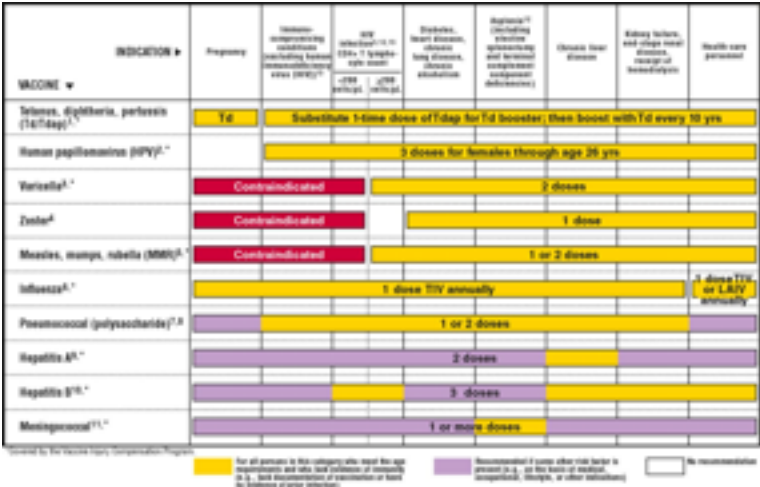

1289
1290

Figure A-1 Recommended adult immunization schedule, United States, 2009.

1290
1291

Figure A-2 Vaccines that might be indicated for adults based on medical and other conditions, 2009.

for healthcare personnel and pregnant women, birth before 1980 should not be considered evidence of immunity); (3) history of varicella based on diagnosis or verification of varicella by a healthcare provider (for a patient reporting a history of or presenting with an atypical case, a mild case, or both, healthcare providers should seek either an epidemiologic link with a typical varicella case or to a laboratory-confirmed case or evidence of laboratory confirmation, if it was performed at the time of acute disease); (4) history of herpes zoster based on healthcare provider diagnosis or verification of herpes zoster by a healthcare provider; or (5) laboratory evidence of immunity or laboratory confirmation of disease.

Pregnant women should be assessed for evidence of varicella immunity. Women who do not have evidence of immunity should receive the first dose of varicella vaccine upon completion or termination of pregnancy and before discharge from the healthcare facility. The second dose should be administered 4 to 8 weeks after the first dose.

^{111.1.4}4. Herpes Zoster Vaccination

A single dose of zoster vaccine is recommended for adults age 60 years and older regardless of whether they report a prior episode of herpes zoster. Persons with chronic medical conditions may be vaccinated unless their condition constitutes a contraindication.

^{111.1.5}5. Measles, Mumps, Rubella (MMR) Vaccination

^{111.1.5.1}Measles Component.

Adults born before 1957 generally are considered immune to measles. Adults born during or after 1957 should receive one or more doses of MMR unless they have a medical contraindication, documentation of one or more doses, history of measles based on healthcare provider diagnosis, or laboratory evidence of immunity.

A second dose of MMR is recommended for adults who (1) have been recently exposed to measles or are in an outbreak setting; (2) have been vaccinated previously with killed measles vaccine; (3) have been vaccinated with an unknown type of measles vaccine during 1963–1967; (4) are students in postsecondary educational institutions; (5) work in a healthcare facility; or (6) plan to travel internationally.

111.1.5.2 Mumps Component.

Adults born before 1957 generally are considered immune to mumps. Adults born during or after 1957 should receive one dose of MMR unless they have a medical contraindication, history of mumps based on healthcare provider diagnosis, or laboratory evidence of immunity.

A second dose of MMR is recommended for adults who (1) live in a community experiencing a mumps outbreak and are in an affected age group; (2) are students in postsecondary educational institutions; (3) work in a healthcare facility; or (4) plan to travel internationally. For unvaccinated healthcare personnel born before 1957 who do not have other evidence of mumps immunity, administering one dose on a routine basis should be considered and administering a second dose during an outbreak should be strongly considered.

111.1.5.3 Rubella Component.

One dose of MMR vaccine is recommended for women whose rubella vaccination history is unreliable or who lack laboratory evidence of immunity. For women of child-bearing age, regardless of birth year, rubella immunity should be determined and women should be counseled regarding congenital rubella syndrome. Women who do not have evidence of immunity should receive MMR upon completion or termination of pregnancy and before discharge from the healthcare facility.

111.1.6 6. Influenza Vaccination

111.1.6.1 Medical Indications.

Vaccinate persons with chronic disorders of the cardiovascular or pulmonary systems, including asthma; chronic metabolic diseases, including diabetes mellitus, renal or hepatic dysfunction, hemoglobinopathies, or immunocompromising conditions (including immunocompromising conditions caused by medications or human immunodeficiency virus [HIV]); any condition that compromises respiratory function or the handling of respiratory secretions or that can increase the risk of aspiration (eg, cognitive dysfunction, spinal cord injury, or seizure disorder or other neuromuscular disorder); and pregnancy during the influenza season. No data exist on the risk for severe or complicated influenza disease among persons with asplenia; however, influenza is a risk factor for secondary bacterial infections that can cause severe disease among persons with asplenia.

111.1.6.2 Occupational Indications.

Vaccinate all healthcare personnel, including those employed by long-term care and assisted-living facilities, and caregivers of children less than 5 years old.

111.1.6.3 Other Indications.

Vaccinate residents of nursing homes and other long-term care and assisted-living facilities; persons likely to transmit influenza to persons at high risk (eg, in-home household contacts and caregivers of children less than 5 years old, persons 65 years old and older, and persons of all ages with high-risk condition[s]); and anyone who would like to decrease their risk of getting influenza. Healthy, nonpregnant adults less than 50 years of age without high-risk medical conditions who are not contacts of severely immunocompromised persons in special care units can receive either intranasally administered live, attenuated influenza vaccine (FluMist) or inactivated vaccine. Other persons should receive the inactivated vaccine.

111.1.7 7. Pneumococcal Polysaccharide (PPSV) Vaccination

111.1.7.1 Medical Indications.

Vaccinate persons with chronic lung disease (including asthma); chronic cardiovascular diseases; diabetes mellitus; chronic liver diseases (including cirrhosis); chronic alcoholism; chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (eg, sickle cell disease or splenectomy [if elective splenectomy is planned, vaccinate at least 2 weeks before surgery]); immunocompromising conditions; and cochlear implants and cerebrospinal fluid leaks. Vaccinate as close to HIV diagnosis as possible.

111.1.7.2 Other Indications.

Vaccinate residents of nursing homes or long-term care facilities and persons who smoke cigarettes. Routine use of PPSV is not recommended for Alaskan Native or American Indian persons younger than 65 years unless they have underlying medical conditions that are PPSV indications. However, public health authorities may consider recommending PPSV for Alaskan Natives and American Indians 50 through 64 years of age who are living in areas in which the risk of invasive pneumococcal disease is increased.

^{111.1.8}8. Revaccination with PPSV

Give one-time revaccination after 5 years for persons with chronic renal failure or nephrotic syndrome; functional or anatomic asplenia (eg, sickle cell disease or splenectomy); and immunocompromising conditions. For persons age 65 years and older, give one-time revaccination if they were vaccinated 5 or more years previously and were less than at age 65 years the time of primary vaccination.

1291

1292

^{111.1.9}9. Hepatitis A Vaccination

^{111.1.9.1}Medical Indications.

Vaccinate persons with chronic liver disease and persons who receive clotting factor concentrates.

^{111.1.9.2}Behavioral Indications.

Vaccinate men who have sex with men and persons who use illegal drugs.

^{111.1.9.3}Occupational Indications.

Vaccinate persons working with hepatitis A virus (HAV)–infected primates or with HAV in a research laboratory setting.

^{111.1.9.4}Other Indications.

Vaccinate persons traveling to or working in countries that have high or intermediate endemicity of hepatitis A (a list of countries is available at www.cdc.gov/travel/content/diseases.aspx) and any person seeking protection from HAV infection.

Single-antigen vaccine formulations should be administered in a two-dose schedule at either 0 and 6 to 12 months (Havrix), or 0 and 6 to 18 months (Vaqta). If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, administer three doses at 0, 1, and 6 months; alternatively, a four-dose schedule, administered on days 0, 7, and 21 to 30 followed by a booster dose at month 12 may be used.

¹¹¹... 10. Hepatitis B Vaccination

^{111.1.1}... Medical Indications.

Vaccinate persons with end-stage renal disease, including patients receiving hemodialysis; persons with HIV infection; and persons with chronic liver disease.

^{111.1.1}... Occupational Indications.

Vaccinate healthcare personnel and public safety workers who are exposed to blood or other potentially infectious body fluids.

^{111.1.1}... Behavioral Indications.

Vaccinate sexually active persons who are not in a long-term, mutually monogamous relationship (eg, persons with more than one sex partner during the previous 6 months); persons seeking evaluation or treatment for a sexually transmitted disease (STD); current or recent injection-drug users; and men who have sex with men.

^{111.1.1}... Other Indications.

Vaccinate household contacts and sex partners of persons with chronic hepatitis B virus (HBV) infection; clients and staff members of institutions for persons with developmental disabilities; international travelers to countries with high or intermediate prevalence of chronic HBV infection (a list of countries is available at www.cdc.gov/travel/content/diseases.aspx); and any adult seeking protection from HBV infection.

Hepatitis B vaccination is recommended for all adults in the following settings: STD treatment facilities; HIV testing and treatment facilities; facilities providing drug-abuse treatment and prevention services; healthcare settings targeting services to injection-drug users or men who have sex with men; correctional facilities; end-stage renal disease programs and facilities for chronic hemodialysis patients; and institutions and nonresidential day care facilities for persons with developmental disabilities.

If the combined hepatitis A and hepatitis B vaccine (Twinrix) is used, administer three doses at 0, 1, and 6 months; alternatively, a four-dose schedule, administered on days 0, 7, and 21 to 30 followed by a booster dose at month 12 may be used.

^{111.1.1...} Special Formulation Indications.

For adult patients receiving hemodialysis or with other immunocompromising conditions, give one dose of 40 mcg/mL (Recombivax HB) administered on a three-dose schedule or two doses of 20 mcg/mL (Engerix-B) administered simultaneously on a four-dose schedule at 0, 1, 2, and 6 months.

^{111....} 11. Meningococcal Vaccination

^{111.1.1...} Medical Indications.

Vaccinate adults with anatomic or functional asplenia, or terminal complement component deficiencies.

^{111.1.1...} Other Indications.

Vaccinate first-year college students living in dormitories; microbiologists who are routinely exposed to isolates of *Neisseria meningitidis*; military recruits; and persons who travel to or live in countries in which meningococcal disease is hyperendemic or epidemic (eg, the “meningitis belt” of sub-Saharan Africa during the dry season [December through June]), particularly if their contact with local populations will be prolonged. Vaccination is required by the government of Saudi Arabia for all travelers to Mecca during the annual Hajj.

Meningococcal conjugate (MCV) vaccine is preferred for adults with any of the preceding indications who are age 55 years or younger, although meningococcal polysaccharide vaccine (MPSV) is an acceptable alternative. Revaccination with MCV after 5 years might be indicated for adults previously vaccinated with MPSV who remain at increased risk for infection (eg, persons residing in areas in which disease is epidemic).

^{111....} 12. Selected Conditions for Which *Haemophilus influenzae* Type b (Hib) Vaccine May Be Used

Hib vaccine generally is not recommended for persons age 5 years and older. No efficacy data are available on which to base a recommendation concerning use of Hib vaccine for older children and adults. However, studies suggest good immunogenicity in persons who have sickle cell disease, leukemia, or HIV infection or who have had a splenectomy; administering one dose of vaccine to these persons is not contraindicated.

^{111....} 13. Immunocompromising Conditions

Inactivated vaccines generally are acceptable (eg, pneumococcal, meningococcal, and influenza [trivalent inactivated influenza vaccine]), and live virus vaccines generally are avoided in persons with immune deficiencies or immunocompromising conditions. Information on specific conditions is available at www.cdc.gov/vaccines/pubs/acip-list.htm.

¹¹²APPENDIX B Guide to Gender-Related Drugs

The purpose of this guide is to help you locate gender-specific drug content, which is scattered throughout the book. Chapter numbers are in **bold** type and page numbers are in parentheses.

^{11...}Drugs Used in Pregnancy

Basic principles of drug use during pregnancy	9 (85-86)
Folic acid supplements	80 (960)
Iron supplements	54 (635)
Hypertension of pregnancy	46 (512)
Chronic hypertension	46 (512)
Preeclampsia and eclampsia	46 (512)
Seizure disorders during pregnancy	24 (234)
Epilepsy	24 (234)
Eclampsia	46 (512)
Diabetes in pregnancy	56 (660)

^{11...}Drugs Used in Labor

Suppression of preterm labor	63 (760-763)
Induction of labor with oxytocin	63 (763-765)
Induction of cervical ripening with dinoprostone	63 (766-767)
Obstetric analgesia	28 (277)

^{11...} Drugs Used in Perinatal Therapy

Control of postpartum hemorrhage	
Ergot alkaloids	63 (765)
Carboprost tromethamine	63 (766)
Respiratory distress syndrome in preterm infants	106 (1255)
Antenatal glucocorticoids for	106 (1255)
Lung surfactants for	106 (1255)
Vitamin K ₁	80 (953-957)
Rh ₀ (D) immune globulin	68 (819)
Hepatitis B vaccine and hepatitis B immune globulin	67 (809)
Gonococcal neonatal ophthalmia	94 (1136)

^{11...} Drugs and Breast-Feeding

Basic principles of drug use during breast-feeding	9 (89-90)
--	------------------

^{11...} Drugs for Women's Health Disorders

Estrogen therapy after menopause	60 (725-732)
Testosterone therapy after menopause	64 (772-773)
Hypoactive sexual desire disorder	64 (772)
Osteoporosis	74 (881-883)
Endometriosis	62 (753)
Infertility	62 (752-759)
Polycystic ovary syndrome	62 (753)
Premenstrual syndrome	60 (723-724)
Amenorrhea	60 (725)
Dysfunctional uterine bleeding	60 (725)
Urinary tract infections	88 (1032-1036)
Vulvovaginal candidiasis	91 (1064)
Breast cancer	102 (1200-1204)

^{11...} Drugs Used to Prevent or Terminate Pregnancy

Oral contraceptives	61 (738-743)
Long-acting contraceptives	61 (744-745)
Emergency contraception	61 (747-748)
Drugs for medical abortion	61 (746-749)
Mifepristone (RU 486) plus misoprostol	61 (746-748)
Other abortifacients	61 (748-749)

^{11...} Drugs for Male Health Disorders

Benign prostatic hyperplasia	65 (781-783)
Erectile dysfunction (impotence)	65 (777-781)
Hypogonadism	64 (771)
Delayed puberty	64 (773)
Prostate cancer	102 (1197-1200)
Reduced libido	64 (772)

^{11...} Drugs for Sexually Transmitted Diseases (STDs)

Drugs for HIV infection	93 (1087-1131)
Drugs for STDs other than HIV infection	94 (1132-1139)
Drugs for venereal warts	104 (1239)

¹¹³APPENDIX C Commonly Used Abbreviations

Abbreviations highlighted in red can be easily misinterpreted, and hence should not be used, as mandated by The Joint Commission (TJC), formerly known as the Joint Commission on Accreditation of Healthcare Organizations (JCAHO). **Abbreviations highlighted in blue** are less likely to be misinterpreted, and hence may still be used, although the alternatives listed are preferred. [Table 7-7](#) in [Chapter 7](#) indicates potential misinterpretations of the highlighted entries.

Ac	before meals (<i>ante cibum</i>)
ACE	angiotensin-converting enzyme
ACh	acetylcholine
ad lib	freely as desired (<i>ad libitum</i>)
ADHD	attention-deficit/hyperactivity disorder
ADLs	activities of daily living
ADP	adenosine diphosphate
AED	antiepileptic drug
AIDS	acquired immunodeficiency syndrome
ALT	alanine aminotransferase (formerly known as SGPT)
AMI	acute myocardial infarction
AMP	adenosine monophosphate
ANA	antinuclear antibodies
ARB	angiotensin II receptor blocker
ARC	AIDS-related complex
ASA	acetylsalicylic acid (aspirin)
AST	aspartate aminotransferase (formerly known as SGOT)
ATP	adenosine triphosphate
AV	atrioventricular
AZT	zidovudine (azidothymidine)
bid	two times a day (<i>bis in die</i>)
bin	two times a night (<i>bis in nocte</i>)
bol	bolus
BP	blood pressure
BPH	benign prostatic hyperplasia
BUN	blood urea nitrogen
C	Celsius (centigrade)
CABG	coronary artery bypass graft
CAD	coronary artery disease
cAMP	cyclic adenosine 3', 5'-monophosphate
CAT	computed axial tomography
CBC	complete blood count
cc	cubic centimeter (milliliter)

Pharmacology for Nursing Care, 7th Edition

CCB	calcium channel blocker
CDC	Centers for Disease Control and Prevention
CHF	congestive heart failure
CMV	cytomegalovirus
CNS	central nervous system
COMT	catechol-O -methyltransferase
COPD	chronic obstructive pulmonary disease
COX	cyclooxygenase
CPK	creatine phosphokinase
CPZ	compazine
CSF	cerebrospinal fluid
CT	computed tomography
CTZ	chemoreceptor trigger zone
CVA	cerebrovascular accident
DBP	diastolic blood pressure
DC	direct current
DKA	diabetic ketoacidosis
dL	deciliter (100 mL)
DMARD	disease-modifying antirheumatic drug
DNA	deoxyribonucleic acid
DPI	dry-powder inhaler
DS	double strength
ECG, EKG	electrocardiogram
ECT	electroconvulsive therapy
EEG	electroencephalogram
F	Fahrenheit
FDA	Food and Drug Administration
FEV	forced expiratory volume
FFA	free fatty acid
g	gram
G6PD	glucose-6-phosphate dehydrogenase
GABA	gamma-aminobutyric acid
GERD	gastroesophageal reflux disease
GFR	glomerular filtration rate

Pharmacology for Nursing Care, 7th Edition

GI	gastrointestinal	
GMP	guanosine monophosphate	
gr	grain	
GTP	guanosine triphosphate	
GU	genitourinary	
h, hr	hour	
H ₂ RA	histamine ₂ -receptor antagonist	
HAART	highly active antiretroviral therapy	
HBGM	home blood glucose monitoring	
HDL	high-density lipoprotein	
HF	heart failure	
HIV	human immunodeficiency virus	
HRT	hormone replacement therapy	
H.S.	half strength; at bedtime	
hs	at bedtime (hour of sleep; <i>hora somni</i>)	
HSV	herpes simplex virus	
HT	hormone therapy	
IBD	inflammatory bowel disease	
ICP	intracranial pressure	
IM	intramuscular, intramuscularly	
IN	intranasal	
INR	international normalized ratio	
IOP	intraocular pressure	
IPV	inactivated polio vaccine	1294
ISA	intrinsic sympathomimetic activity	1295
IU	international unit	
IUD	intrauterine device	
IV	intravenous, intravenously	
kg	kilogram	
KVO	keep vein open	
L	liter	
LD	lethal dose	
LDL	low-density lipoprotein	

Pharmacology for Nursing Care, 7th Edition

LGV	lymphogranuloma venereum
LSD	D-lysergic acid diethylamide
m	minim
MAC	minimum alveolar concentration; <i>Mycobacterium avium</i> complex
MAO	monoamine oxidase
MAOI	monoamine oxidase inhibitor
MAP	mean arterial pressure
MBC	minimum bactericidal concentration
mcg, μg	microgram
MDI	metered-dose inhaler
MEC	minimum effective concentration
mEq	milliequivalent
mg	milligram
MgSO₄	magnesium sulfate
MHC	major histocompatibility complex
MI	myocardial infarction
MIC	minimum inhibitory concentration
mL	milliliter
mM	millimolar
mmol	millimole
MMR	measles, mumps, rubella
mOsm	milliosmole
MRI	magnetic resonance imaging
MS	morphine sulfate
MSO₄	morphine sulfate
MTX	methotrexate
ng	nanogram
NGU	nongonococcal urethritis
NNRTI	non-nucleoside reverse transcriptase inhibitor
NPO	nothing by mouth (<i>nil per os</i>)
NRTI	nucleoside/nucleotide reverse transcriptase inhibitor
NSAID	nonsteroidal anti-inflammatory drug
OC	oral contraceptive

Pharmacology for Nursing Care, 7th Edition

OD	right eye (<i>oculus dexter</i>)
OPV	oral polio vaccine
OS	left eye (<i>oculus sinister</i>)
OTC	over-the-counter
OU	both eyes (<i>oculus uterque</i>)
PABA	<i>para</i> -aminobenzoic acid
pc	after meals (<i>post cibum</i>)
PCP	<i>Pneumocystis</i> pneumonia
PEFR	peak expiratory flow rate
PET	positron emission tomography
pg	picogram
PG	prostaglandin
PID	pelvic inflammatory disease
PMS	premenstrual syndrome
PO	by mouth (<i>per os</i>)
PPD	purified protein derivative (tuberculin)
PPI	proton pump inhibitor
PR	by the rectum (<i>per rectum</i>)
PRN	as needed (<i>pro re nata</i>)
PT	prothrombin time
PTCA	percutaneous transluminal coronary angioplasty
PTT	partial thromboplastin time
PVC	premature ventricular contraction
qd	every day (<i>quaque die</i>)
qh	every hour (<i>quaque hora</i>)
qid	four times a day (<i>quater in die</i>)
qod	every other day
RA	rheumatoid arthritis
RBC	red blood cell (erythrocyte)
RDA	recommended dietary allowance
REM	rapid eye movement
RNA	ribonucleic acid
SA	sinoatrial
SAARD	slow-acting antirheumatic drug

Pharmacology for Nursing Care, 7th Edition

SBP	systolic blood pressure
SGOT	serum glutamic-oxaloacetic transaminase (now known as AST)
SGPT	serum glutamic-pyruvic transaminase (now known as ALT)
sl	sublingual
SLE	systemic lupus erythematosus
SPF	sun protection factor
SR	sarcoplasmic reticulum; sustained release
SSRI	selective serotonin reuptake inhibitor
stat	immediately
STD	sexually transmitted disease
subQ, SC, SQ	subcutaneous, subcutaneously
SVT	supraventricular tachycardia
TIA	transient ischemic attack
tid	three times a day (<i>ter in die</i>)
U	unit
UTI	urinary tract infection
VLDL	very-low-density lipoprotein
VSM	vascular smooth muscle
WBC	white blood cell (leukocyte)

¹¹⁴APPENDIX D Canadian Drug Information

ALFRED J. RÉMILLARD, PharmD BCPP

^{11...}INTERNATIONAL SYSTEM OF UNITS

In an attempt to standardize the large number of different units used worldwide and thus improve communication, the *Système International d'Unités* (International System of Units; SI) was recommended in 1954. In 1971, the mole (mol) was adopted as the standard for designating the amount of substance present, and the liter (L) was adopted as the standard for designating volume. The World Health Organization recommended the adoption of SI units in 1977. However, Canada had already implemented an equivalent system in 1971.

In the area of therapeutics, the major change caused by adopting the SI was to express drug concentrations present in body fluids in molar units (eg, mmol/L) rather than in mass units (eg, mg/L). This allows a better comparison between the pharmacologic and pharmacodynamic effects of different drugs, since these properties are relative to the number of molecules (eg, mmol) of drug present rather than to the number of mass units (eg, mg).

^{11...}DRUG SERUM CONCENTRATIONS

Many drugs have known therapeutic or toxic levels that are monitored in patients to ensure safety and efficacy. In Canada, clinical laboratories report these levels in SI units. Levels traditionally reported as milligrams per milliliter (mg/mL) can be converted to millimoles per liter (mmol/L) using the conversion factor (CF) for that specific drug: $CF = 1000 / \text{molecular weight of the drug}$

To convert from micrograms per milliliter to SI units, the following equation is used: $\text{mcg} / \text{mL} \times CF = \text{micromoles} / \text{L}$

To convert from SI units to micrograms per milliliter, the following equation is used:
 $(\text{micromoles} / \text{L}) / CF = \text{mcg} / \text{mL}$

[Table D-1](#) lists some important drugs for which therapeutic or toxic levels have been established. For most of these drugs, the levels presented are trough (minimum) values, which are measured in blood samples drawn just prior to the next dose. For the aminoglycosides and vancomycin, two levels are listed: a trough level and a peak (maximum) level. Levels must remain between the peak and trough to ensure efficacy of these drugs and at the same time to minimize toxicity.

^{11...} CANADIAN DRUG LEGISLATION

Two acts form the basis of the drug laws in Canada: the Food and Drug Act and the Controlled Drugs and Substance Act. The responsibility for administering these acts rests with the Therapeutic Products Directorate (TPD) at Health Canada.

The Food and Drug Act (1927), accompanied by the Food and Drug Regulations (1953, 1954, 1979), reviews the safety and efficacy of drugs before they are marketed, and the legislation determines whether the medicine is classified as prescription or nonprescription status. The Act controls the requirements for good manufacturing practices, labeling, distribution, and sale, including advertising of the drug.

^{114.3.1} Prescription Drugs (Schedule F)

All drugs that require a prescription, except for narcotics and controlled substances, are listed in Schedule F of the Food and Drug Regulations. Prescriptions for Schedule F medications may be written (including facsimiles) or transmitted orally (ie, telephone order directly to the pharmacist) by a duly qualified medical practitioner, dentist, veterinarian, or other healthcare professional authorized to issue prescriptions. The prescription can be refilled as often as indicated by the

physician. The symbol  must appear on all manufacturing labels. Individual provinces

can legislate more restrictive control and require a prescription for a medication classified by the TPD as a nonprescription drug (eg, digoxin).

The Controlled Drugs and Substance Act (1997) establishes the requirements for the control and sale of narcotics, controlled drugs, and substances of abuse in Canada. The Controlled Drugs and Substance Act lists eight schedules of controlled substances. Assignment to a schedule is based on potential for abuse and the ease with which illicit substances can be manufactured in illegal laboratories. The degree of control, the conditions of record keeping, and other regulations depend on the specific schedule. For example, Schedule I, which includes the narcotic agents, requires written orders only, and no repeat prescriptions are allowed. Some provinces require prescriptions for certain narcotics, such as morphine, to be written on a triplicate prescription

form with one copy to be sent to the practitioner's regulatory body. The symbol  must

appear on the labels of controlled products, while the letter N is printed on the label of all the narcotic agents. Schedules I through VIII are defined below. In the fall of 2000, all the

1296

1297

Pharmacology for Nursing Care, 7th Edition

benzodiazepines were classified as “targeted substances,” and the symbol ‘t/c’ must now appear on all the labels.

- Schedule I: opium poppy and its derivatives (eg, morphine, heroin); methadone; coca and its derivatives (eg, cocaine)

TABLE D-1 Therapeutic Serum Drug Concentrations

Drugs	SI Reference Interval	SI Unit	Conversion Factor	Traditional Reference Interval	Traditional Reference Unit
Acetaminophen	13–40	micromol/L	66.15	0.2–0.6	mg/dL
Acetylsalicylic acid	7.2–21.7	micromol/L	0.0724	100–300	mg/dL
Amikacin*	—	—	—	15–25†; <8‡	mcg/mL
Amitriptyline	430–900§	nmol/L	3.605	120–250§	ng/mL
Carbamazepine	17–42	micromol/L	4.233	4–10	mcg/mL
Desipramine	430–750	nmol/L	3.754	115–200	ng/mL
Digoxin	0.6–2.8	nmol/L	1.282	0.5–2.2	ng/mL
Disopyramide	6–18	micromol/L	2.946	2–6	mcg/mL
Gentamicin*	—	—	—	6–10†; <2‡	mcg/mL
Imipramine	640–1070§	nmol/L	3.566	180–300§	ng/mL
Lidocaine	4.5–21.5	micromol/L	4.267	1–5	mcg/mL
Lithium	0.4–1.2	mmol/L	1	0.4–1.2	mEq/L
Netilmicin*	—	—	—	6–10†; <2‡	mcg/mL
Nortriptyline	190–570	nmol/L	3.797	50–150	ng/mL
Phenobarbital	65–170	micromol/L	4.306	15–40	mcg/mL
Phenytoin	40–80	micromol/L	3.964	10–20	mcg/mL
Primidone	25–46	micromol/L	4.582	6–10	mcg/mL
Procainamide	17–34§	micromol/L	4.249	4–8‡	mcg/mL
Quinidine	4.6–9.2	micromol/L	3.082	1.5–3	mcg/mL
Theophylline	55–110	micromol/L	5.55	10–20	mcg/mL
Tobramycin*	—	—	—	6–10†; <2‡	mcg/mL
Valproic acid	300–700	micromol/L	6.934	50–100	mcg/mL
Vancomycin*	—	—	—	25–40†; <10‡	mcg/mL

Pharmacology for Nursing Care, 7th Edition

*	Aminoglycosides (amikacin, gentamicin, netilmicin, tobramycin) and vancomycin are not reported in SI units because of the variability of their molecular weights.
†	Peak drug level.
‡	Trough drug level.
§	Drug level reported as the total of the parent drug and its active metabolite.

- Schedule II: cannabis and its derivatives (eg, marijuana, hashish)
- Schedule III: amphetamines, methylphenidate, lysergic acid diethylamide (LSD), methaqualone, psilocybin, mescaline
- Schedule IV: sedative-hypnotic agents (eg, barbiturates, benzodiazepines); anabolic steroids
- Schedule V: Propylhexedrine and any salt thereof
- Schedule VI: Compounds that can serve as precursors for manufacturing controlled substances

Part 1: Class A Precursors. Acetic anhydride, Nacetylanthranilic acid, anthranilic acid, ephedrine; ergometrine, ergotamine, isosafrole, lysergic acid, 3,4-methylenedioxyphenyl-2-propanone, norephedrine, 1-phenyl-2-propanone, phenylacetic acid, piperidine, piperonal, potassium permanganate, pseudoephedrine, safrole, gamma-butyrolactone, 1,4butanediol, red and white phosphorus, hypophosphorous acid, hydriodic acid

Part 2: Class B Precursors. Acetone, ethyl ether, hydrochloric acid, methyl ethyl ketone, sulphuric acid, toluene

Part 3: Any preparation or mixture that contains a precursor set out in Part 1 or in Part 2

Schedule VII: Cannabis resin 3 kg; Cannabis (marihuana) 3 kg

Schedule VIII: Cannabis resin 1 g; Cannabis (marihuana) 30 g

The Controlled Drugs and Substance Act also provides for the nonprescription sale of certain codeine preparations. The content must not exceed the equivalent of 8 mg codeine phosphate per

solid dosage unit or 20 mg/30 mL of a liquid, and the preparation must also contain two additional non-narcotic medicinal ingredients (usually acetylsalicylic acid or acetaminophen and caffeine). These preparations may not be advertised or displayed and may be sold only by pharmacists. Some provinces restrict the amount that can be sold at any given time.

1297

114.3.2 Nonprescription Medications

1298

Currently there are three categories of nonprescription medications that govern their sale. Restricted Access Nonprescription Drugs are “kept behind the counter” and are available for sale directly from the pharmacist only. Examples include insulin, immediate-release nitroglycerin, low-dose codeine preparations, and lindane products. The restriction requires consultation with the pharmacist and referral to a physician when appropriate. For patients already prescribed those medications, their proper use and safety is ensured by the counseling of the pharmacist. The second category is Pharmacy Only Nonprescription Drugs, and as the name implies, these drugs are sold only at pharmacies. These medications are suitable for self-selection, but may pose a risk to certain patient populations and therefore should be sold where the pharmacist is available to provide advice when requested. Examples include high-dose simple analgesics (ie, aspirin, nonsteroidal anti-inflammatory drugs) and antihistamines. The third category includes nonprescription products that can be sold at any retail outlet and do not require professional supervision. In general, these products are provided with adequate information for the patient to make a safe and effective choice, and labeling is believed sufficient enough to permit appropriate use of the drug product. Examples are nicotine gum and patches, low-dose simple analgesics, and antiulcer therapy.

114.3.3 National Drug Schedules

As previously mentioned, individual provinces have enacted their own legislation controlling the sale of both prescription and nonprescription products. This has led to inconsistency and confusion for both the healthcare practitioner and the consumer. As a result, the National Association of Pharmacy Regulatory Authorities (NAPRA) endorsed a proposal for a national drug scheduling model. This model attempts to align the provincial drug schedules so that the conditions for the sale of drugs will be consistent across the country. Unfortunately, NAPRA selected the term *schedules* followed by the same corresponding Roman numerals, which may add some confusion to the current Controlled Drugs schedules. The harmonized model includes all classes of medications. Narcotics, controlled substances, and prescription medications are listed in Schedule I, while nonprescription medications are assigned to one of the three categories previously described. For a complete drug list proposed by NAPRA, visit their web site at www.napra.ca:

- Schedule I: all prescription drugs, including narcotics and controlled substances
- Schedule II: Restricted Access or Pharmacist Only Nonprescription Drugs
- Schedule III: Pharmacy Only Nonprescription Drugs
- Unscheduled Drugs: those drugs not assigned to the above categories, which can be sold at any retail outlet

There is general support among the provincial regulatory bodies for the National Drug Schedules, although there is some disagreement on the actual list of drugs.

^{114.3.4} New Drug Development in Canada

The process for approving a new drug in Canada is very similar, if not identical, to the process in the United States. The same drug data that are required for approval by the Food and Drug Administration in the United States are required by the TPD in Canada. The principal difference between Canada and the United States is one of nomenclature: Once preclinical testing is completed, the manufacturer in Canada applies for a Preclinical New Drug Submission, versus an Investigational New Drug in the United States. At the end of clinical testing, the manufacturer in Canada seeks a New Drug Submission (NDS), versus a New Drug Application in the United States.

After all the information on a new drug has been submitted—including results of preclinical and clinical testing, method of manufacturing, packaging, labeling, and results of stability testing—the pharmaceutical company receives a Notice of Compliance (NOC) from the TPD, and the drug enters the market.

Although data collection for a new drug is thorough, there is no guarantee that all adverse reactions are known, especially when the drug is used concurrently with other drugs. Also, long-term effects are not fully appreciated. For these reasons, postmarketing surveillance plays a major role in monitoring new drugs. The Canadian Adverse Drug Reactions monitoring program has undergone extensive expansion in recent years. The manufacturer and all healthcare practitioners must immediately report any new clinical findings, unexpected adverse effects, or therapeutic failures to the TPD.

^{114.3.5} Patent Laws

Patent laws in Canada continue to evolve. In 1969, the Patent Act was changed to include compulsory licensing. This new provision allowed generic drug companies to manufacture and distribute patented drugs in Canada, provided that a minimal 4% royalty fee was paid to the

patent holder. This system was introduced to help control drug prices. Unfortunately, the system caused a decline in revenue to “innovative” pharmaceutical companies, with a resultant decline in research on new drug development. After much debate, and retroactive to June 1987, the Patent Act was amended to give patent holders market exclusivity either (1) for 7 to 10 years or (2) until the 17-year patent (from date of filing) expires, whichever comes first. The Patent Act was then further amended to “make Canada's intellectual property legislation more in line with that of the major industrialized countries.”

In response to provisions of the North American Free Trade Agreement (NAFTA) and the General Agreement on Tariffs and Trade (GATT), Bill C-91 was introduced in 1993. This bill (1) eliminated compulsory licensing and (2) extended patent protection on brand-name drugs to 20 years, thereby making Canadian patent laws similar to those of the United States and other industrialized nations. Section 14 of Bill C-91 called for a parliamentary review of legislation in 1997. A special committee reviewed the impact of Bill C-91 on such factors as drug prices, drug research and development, and job creation. No changes to the legislation were made.

1298

In order to respond to concerns arising from changes in the Patent Act, a Patented Medicine Prices Review Board was created. Its mandate is to (1) ensure that prices of patented medicines are not excessive and (2) report on the ratios of research and development expenditures relative to sales for individual patentees and for the pharmaceutical industry as a whole. There is, however, some pressure by the pharmaceutical industry to adopt worldwide patent laws for pharmaceutical products.

¹¹⁵APPENDIX E Major Drug Classes and Their Prototypes

The prototypic drugs in this list are classified in two ways: (1) by *pharmacologic family* (eg, beta-adrenergic blockers, opioid analgesics), and (2) by *therapeutic family* (eg, drugs for angina pectoris, drugs for HIV infection). Since a single drug may belong to multiple therapeutic families (in addition to its single pharmacologic family), a drug may appear in the list more than once. Propranolol, for example, appears four times: first as a prototype for its pharmacologic family (beta-adrenergic blockers), and later as a prototype within three therapeutic families (antidysrhythmic drugs, drugs for angina pectoris, and drugs for hypertension).

^{11...} PERIPHERAL NERVOUS SYSTEM DRUGS

^{115.1.1} Muscarinic Antagonists

Atropine

^{115.1.2} Cholinesterase Inhibitors

Neostigmine (reversible inhibitor)

Nonsteroidal Anti-inflammatory Drugs

Aspirin (a first-generation NSAID)

Celecoxib (a COX-2 inhibitor)

Glucocorticoids

Prednisone

Disease-Modifying Antirheumatic Drugs (DMARDs)

Methotrexate (immunosuppressant)

Hydroxychloroquine (immunosuppressant)

Etanercept (tumor necrosis factor blocker)

Rituximab (B-lymphocyte-depleting agent)

Abatacept (T-cell activator)

^{115.9.2}Drugs for Osteoporosis

Antiresorptive Agents

Conjugated equine estrogens [Premarin]

Raloxifene (selective estrogen receptor modulator)

Alendronate (bisphosphonate)

Calcitonin-salmon nasal spray

Bone-Forming Agents

Teriparatide

1303

^{11...} RESPIRATORY TRACT DRUGS

1304

^{115....} Drugs for Asthma

Anti-inflammatory Drugs: Glucocorticoids

Beclomethasone (inhaled)

Prednisone (oral)

Anti-inflammatory Drugs: Others

Cromolyn (mast cell stabilizer)

Zafirlukast (leukotriene modifier)

Bronchodilators: Beta₂-Adrenergic Agonists

Terbutaline (inhaled, short acting)

Salmeterol (inhaled, long acting)

Albuterol (oral)

Bronchodilators: Methylxanthines

Theophylline

Anticholinergic Drugs

Ipratropium

^{11...} GASTROINTESTINAL DRUGS

^{115....} Drugs for Peptic Ulcer Disease

Antibiotics (for Helicobacter pylori)

Amoxicillin/clarithromycin/omeprazole

H₂-Receptor Antagonists

Cimetidine

Proton Pump Inhibitors

Omeprazole

Mucosal Protectants

Sucralfate

Muscarinic Antagonists

Pirenzepine

Antacids

Aluminum hydroxide/magnesium hydroxide

Drugs for NSAID-Induced Ulcers

Misoprostol

^{115....} Laxatives

Bulk-Forming Agents

Methylcellulose

Surfactants

Docusate sodium

Stimulant Laxatives

Bisacodyl

Osmotic Laxatives

Magnesium hydroxide

Chloride Channel Activator

Lubiprostone

¹¹⁵.... Antiemetics

Serotonin Antagonists

Ondansetron

Glucocorticoids

Dexamethasone

Substance P/Neurokinin₁ Antagonists

Aprepitant

Dopamine Antagonists

Prochlorperazine

Cannabinoids

Dronabinol

Benzodiazepines

Lorazepam

¹¹⁵.... Drugs for Inflammatory Bowel Disease

5-Aminosalicylates

Sulfasalazine

Glucocorticoids

Budesonide

Immunomodulators/Immunosuppressants

Mercaptopurine

Infliximab

^{115....} Drugs for Irritable Bowel Syndrome (IBS)

Drugs for Constipation-Predominant IBS

Lubiprostone

Drugs for Diarrhea-Predominant IBS

Alosetron

^{11...} DRUGS FOR BACTERIAL INFECTIONS

^{115....} Penicillins, Cephalosporins, and Other Drugs That Weaken the Bacterial Cell Wall

Penicillins

Penicillin G

Cephalosporins

Cephalothin

Others

Imipenem

Vancomycin

^{115....} Bacteriostatic Inhibitors of Protein Synthesis

Tetracyclines

Tetracycline

Macrolides

Erythromycin

Oxazolidinones

Linezolid

Glycylcyclines

Tigecycline

Others

Clindamycin

^{115....} Aminoglycosides (Bactericidal Inhibitors of Protein Synthesis)

Gentamicin

^{115....} Fluoroquinolones

Ciprofloxacin

¹¹⁵.... Cyclic Lipopeptides

Daptomycin

¹¹⁵.... Sulfonamides and Trimethoprim

Sulfisoxazole

Trimethoprim

Trimethoprim/sulfamethoxazole [Bactrim]

¹¹⁵.... Drugs for Tuberculosis

Isoniazid

Rifampin

Pyrazinamide

Ethambutol

1304

¹¹... DRUGS FOR FUNGAL INFECTIONS

1305

Polyene Macrolides

Amphotericin B

Azoles

Itraconazole

Echinocandins

Caspofungin

^{11...} DRUGS FOR VIRAL INFECTIONS

^{115....} Drugs for Cytomegalovirus Infection

Ganciclovir

^{115....} Drugs for Hepatitis

Hepatitis B

Peginterferon alfa-2b

Lamivudine

Hepatitis C

Peginterferon alfa-2a

Ribavirin (oral)

^{115....} Drugs for Influenza

Vaccines

Influenza vaccine

Neuraminidase Inhibitors

Oseltamivir

Adamantanes

Amantadine

¹¹⁵.... Drugs for Respiratory Syncytial Virus Infection

Ribavirin (inhaled)

Palivizumab

¹¹⁵.... Drugs for HIV Infection

Nucleoside Reverse Transcriptase Inhibitors

Azidothymidine

Non-nucleoside Reverse Transcriptase Inhibitors

Efavirenz

Protease Inhibitors

Lopinavir (boosted with ritonavir)

HIV Fusion Inhibitors

Enfuvirtide

CCR5 Antagonists

Maraviroc

Integrase Inhibitors

Raltegravir

^{11...} ANTICANCER DRUGS: CYTOXIC AGENTS

Alkylating Agents

Cyclophosphamide

Platinum Compounds

Cisplatin

Antimetabolites

Methotrexate (folic acid analog)

Fluorouracil (pyrimidine analog)

Mercaptopurine (purine analog)

Antitumor Antibiotics

Doxorubicin (an anthracycline)

Dactinomycin (a nonanthracycline)

Mitotic Inhibitors

Vincristine (a vinca alkaloid)

Paclitaxel (a taxoid)

Topoisomerase Inhibitors

Etoposide

Others

Asparaginase

¹¹... ANTICANCER DRUGS: HORMONAL AGENTS, BIOLOGIC RESPONSE MODIFIERS, AND TARGETED DRUGS

¹¹⁵... Glucocorticoids

Prednisone

^{115.16}... Drugs for Prostate Cancer

Gonadotropin-Releasing Hormone Analogs

Leuprolide

Androgen Receptor Blockers

Flutamide

^{115.16}... Drugs for Breast Cancer

Antiestrogens

Tamoxifen

Aromatase Inhibitors

Anastrozole

HER2 Antagonists

Tamoxifen

Cytotoxic Drugs

Doxorubicin/cyclophosphamide

Paclitaxel

^{115.16....} Biologic Response Modifiers: Immunostimulants

Interferons

Interferon alfa-2a

Others

Aldesleukin

^{115.16....} Targeted Drugs

EGFR-Tyrosine Kinase Inhibitors

Cetuximab

BRC-ABL Tyrosine Kinase Inhibitors

Imatinib

CD20-Directed Antibodies

Rituximab

Angiogenesis Inhibitors

Bevacizumab

Proteasome Inhibitors

Bortezomib

Others

Trastuzumab

Alemtuzumab

¹¹⁶ APPENDIX F Very New Drugs and Important New Formulations of Older Drugs

The products in this table were approved too late for inclusion in the text. Information on these and other new drugs will be available on our web site, evolve.elsevier.com/Lehne/, beginning in the winter of 2009.

Generic Name	Trade Name	Description
Amoxicillin	Moxatag	A once-daily, extended-release formulation of amoxicillin for tonsillitis and/or pharyngitis caused by <i>Streptococcus pyogenes</i>
Dexlansoprazole	Kapidex	The R-isomer of lansoprazole [Prevacid], a proton pump inhibitor for reducing GI acidity
Eltrombopag	Promacta	A thrombopoietin receptor agonist used to treat refractory thrombocytopenia in patients with chronic immune (idiopathic) thrombocytopenic purpura
Everolimus	Afinitor	An inhibitor of the molecular target of rapamycin indicated for refractory renal cell carcinoma
Fesoterodine	Toviaz	An antimuscarinic drug for oral therapy of overactive bladder
Fospropofol	Lusedra	A water-soluble prodrug form of propofol, a sedative/hypnotic used for induction and maintenance of anesthesia (see Chapter 27)
Iloperidone	Fanapt	A second-generation antipsychotic agent that blocks dopamine D ₂ receptors and serotonin 5HT _{2A} receptors
Lacosamide	Vimpat	An antiepileptic agent for oral or parenteral therapy of partial-onset seizures
Mesalamine	Apriso	An extended-release, once-daily formulation of mesalamine for ulcerative colitis (see Chapter 79)
Plerixafor	Mozobil	A CXCR4 antagonist used in conjunction with granulocyte colony-stimulating factor to mobilize hematopoietic stem cells to peripheral blood for collection prior to autologous transplantation in patients with non-Hodgkin's lymphoma and multiple myeloma
Romiplostim	Nplate	A thrombopoietin receptor agonist used to treat refractory thrombocytopenia in patients with chronic immune (idiopathic) thrombocytopenic purpura
Rufinamide	Banzel	An antiepileptic agent for adjunctive treatment of seizure associated with Lennox-Gastaut syndrome
Tapentadol	None as of 3/10/2009	A mixed-acting mu opioid agonist/norepinephrine reuptake inhibitor for oral therapy of moderate to severe acute pain
Valproic acid	Stavzor	Delayed-release valproic acid

¹¹⁷Special Interest Topics

^{11...}Special Interest Topics

Special interest topics—presented in boxes—highlight information that I find especially interesting and hope you will too. Some boxes address cutting-edge therapies (eg, use of angiogenesis inhibitors in cancer), some address ongoing controversies (eg, use of antibiotics in animal feed), some address important issues of general interest (eg, management of premenstrual syndrome), and some address topics featured in the popular press (eg, use of botulinum toxin to remove frown lines).

Box Number	Page	Title
8-1	80	Has the Placebo Lost Its Effect?
17-1	155	The EpiPen: Don't Leave Home Without It!
21-1	187	Surgical and Electrical Treatments for Parkinson's Disease
24-1	221	Nondrug Therapies for Epilepsy: Neurosurgery, Vagus Nerve Stimulation, and the Ketogenic Diet
30-1	308	Medication Overuse Headache: Too Much of a Good Thing
32-1	337	Postpartum Depression
33-1	362	Omega-3 Fatty Acids for Bipolar Disorder: A Fish Story with a Happy Ending
34-1	374	Melatonin: Hypnotic or Hype?
36-1	396	Did Kisses Kill Calvin?
39-1	426	Date-Rape Drugs: Rohypnol and GHB
46-1	496	Isolated Systolic Hypertension: The Real Killer of Aging Americans
46-2	504	And the Best Drug Is... The Cheap One!
47-1	523	Attention Ladies: Digoxin May Be Hazardous to Your Health
49-1	559	Inflammation, C-Reactive Protein, and Cardiovascular Risk
60-1	723	Premenstrual Syndrome (PMS)
61-1	747	Emergency Contraception
63-1	762	Sure, Drugs Can <i>Delay</i> Preterm Labor, But Can They <i>Prevent</i> It?
64-1	772	Testosterone Replacement: Can It Enhance Sexuality in Men? or Women?
75-1	891	Chronic Obstructive Pulmonary Disease
76-1	913	Zinc for Kids with Colds?
77-1	922	Gastroesophageal Reflux Disease
80-1	956	Losing HOPE for Antioxidants
82-1	975	Antibiotics in Animal Feed: Dying for a Big Mac and Chicken McNuggets
83-1	991	Methicillin-Resistant <i>Staphylococcus aureus</i>
102-1	1212	Angiogenesis Inhibitors: No Flow—No Grow
104-1	1241	Face Time with Botox
106-1	1254	Thalidomide Redeemed—And Strictly Controlled
